CASES OF EYE DISEASES, WITH REMARKS.

By MR. MACKENZIE (*of Glasgow.*)

NO. I.

Differing Cases of the same Disease.

If the apothegm be true in regard to the affections of the body in general, it appears to be still more strikingly so in regard to the affections of the eye in particular—viz. that, in its strict sense, sameness can never be predicated of any two diseases. Take, for example, strumous corneitis: we meet with some cases of this disease in which the symptoms are, from first to last, not only so associated with debility of the system, but so unattended with pain, or any other sign of active inflammation, that we treat them, throughout their whole course, and very effectually, with sulphate of quina; while other cases, even in weakly strumous children, are accompanied with such severe pain (I do not mean intolerance of light, but actual pain) that we are obliged to apply leeches round the eye, perhaps even to take blood from the system, to administer nauseants and purgatives, and to put the patient on a course of calomel and opium. A little common sense will easily enable the attentive practitioner to discriminate such *differing* cases of the *same* disease, and a little experience to decide on the appropriate line of treatment.

Is it not very remarkable that the accidents which befall the eye, the same accidents, are, in different individuals, productive of very dissimilar effects—may, that even when the general effect is

the same, the concomitant effects are sometimes exceedingly unlike?

Dislocation of the Lens.

There came to the Eye Infirmary, on the 22d August, 1831, a case of dislocated lens. As this is a very serious injury, and the case interesting on more accounts than one, I shall shortly state the circumstances which attended it.

CASE I.—James Long, æt. 66, nine weeks ago received a blow, with a piece of wood, on the right eye. The blow appears to have ruptured the capsule, and the lens is lying in front of the iris. Pupil much dilated. He has been greatly distressed since the accident, with circumorbital pain during the night, so that he gets little or no sleep. Not much redness of the eye. Pulse 84. Left eye glaucomatous, and he thinks the vision of this eye has failed since the accident which has happened to the right.

The upper half of the cornea being opened in the usual way, the lens immediately escaped, followed by some dissolved vitreous humour. The lids of both eyes were brought together by strips of court-plaister, and he was desired to keep his eyes quiet, as if he were asleep.

23d.—Slept more last night than he has done since the accident. Complains little or none of the pain. There has been considerable watery discharge from the eye. Pupil remains widely dilated. It is uncertain whether he discerns light with the eye.

24th.—Edges of the incision accurately in apposition. Pupil still dilated, and retina apparently insensible to light.

On the 9th September he was dismissed, the eye perfectly free from un-

easiness, but without any return of vision.

This, then, is a case of rupture of the crystalline capsule, from a blow on the eye; a large hard lens passing through the pupil and lodging in contact with the cornea, lodging there for nine weeks without becoming cataractous or undergoing any sensible diminution of size, but causing incessant uneasiness, and during the night severe circumorbital pain. The practice? Simply extraction of the lens, which, under such circumstances, must be regarded exactly as a foreign body. The patient did not require a single opiate, and had scarcely the least twinge of pain after the lens was removed.

I shall compare this case with some other cases of dislocated lens which have fallen under my observation.

CASE II.—A stout countryman, while working in a quarry, received a blow with a piece of stone on his right eye, four weeks before I saw him. Like a wise man, he put himself under the care of a blacksmith, who allowed him to remain without any thing being done which could effectually relieve him of the incessant and excruciating pain which he suffered in the eye and head. The sclerótica was intensely inflamed, the cornea unnaturally prominent and somewhat hazy, the iris in contact with the cornea, and the lens, broken in pieces and apparently swollen, lying in contact with the iris and cornea. Immediately below the cornea the sclerótica presented a concave depression, the result of the blow.

It was evident that the capsule had burst, and that the lens, being pressed forwards, had obliterated the aqueous chambers; an accident which is always productive of severe pain. I immediately opened the cornea by a small section at its upper edge, and instantly the soft disorganized lens was evacuated. The patient had four grains of calomel and two of opium at bed-time. The pain entirely ceased in the course of the afternoon, and never returned. On the seventh day after the extraction he left Glasgow, to return into the country. There was still considerable zonular redness; shreds of opaque capsule occupied the dilated pupil; the lower part of the sclerótica still presented a concavity, instead of its natural convexity; vision, which, from the violence of the injury and long neglect of proper means

of relief, there was reason to fear had been altogether lost, appeared in some slight degree to be returning, the patient perceiving light and shadow when he looked to his right.

A remarkable circumstance in his case was the permanent flattening given to the sclerótica by the momentary pressure of the stroke. We are not surprised that the eye should be bent for a moment from its natural shape, but that this effect should continue, is a thing not easily explained. We see this, however, happen to the eye not unfrequently; and some time ago the cornea presented itself in this deformed state in a patient of the Eye Infirmary.

CASE III.—An angular fragment of iron, about half an inch long, chipped off by a chisel, penetrated the right cornea of Samuel Lamont, within a line of its upper margin. Though immediately removed, it produced cataract and dislocation of the lens, with very violent inflammation, which continued unabated for five weeks before the patient came to the Eye Infirmary, notwithstanding bloodletting, leeching, and blistering. The lens was extracted by Mr. Rainy, with the same striking relief which extraction generally affords in such cases. The cornea, at his admission, was more convex in its horizontal than in its vertical section, as if it had been compressed laterally. This form, which it permanently retained, served materially to disturb the patient's vision. The retina appeared to be sound, and he saw considerably more distinctly when he viewed objects through a four-inch convex glass.

CASE IV.—On the same day that the countryman came to me, whose case I have already related, Mr. James Brown brought to me, for consultation, a lad of 17, a potter, under the following circumstances. His right eye had been destroyed in childhood. For a considerable time he had been troubled with *muscæ volitantes* before his left eye. On the 1st September he received a very slight blow on this eye, with a bit of potter's clay, thrown at him in sport by one of his fellow-workmen. On the morning of the 4th he found, on rising out of bed, that he saw indistinctly, and went out to wash his eye at a well, supposing that the dimness of sight arose from matter adhering to the eye-lids. This produced no difference in the sight; on which one of his neighbours looked

at the eye, and told him that he saw something wagging in the inside of it. He immediately came to Mr. Brown, who discovered the lens lying at the bottom of the anterior chamber. It seemed quite transparent even on the 5th, when I saw him, and was so much reduced in size as to move freely about on every inclination of the head. Its lower edge, where it rested on the floor of the anterior chamber, was somewhat square, as if absorption had been going on more rapidly there than elsewhere. The upper edge of the pupil was not covered by the lens, so that he saw over it. Belladonna was applied on the afternoon of the 5th, the pupil dilated, and that evening the lens fell back through the pupil into the posterior chamber. Next day he had no pain, and saw well, but the iris was evidently tremulous. The lens will, I have no doubt, dissolve; but the rest of the eye is, unfortunately, not in a sound state, and will probably become amaurotic.

CASE V.—We have an illustration of another variety of dislocation of the lens, in the right eye of Mary Mains, aged 50, whom we admitted at the Eye Infirmary on the 7th September.

A month before her admission, she received a blow with the fist on the right orbital region. The integuments had been divided above the eyebrow, but the wound at her admission was perfectly healed, although the cicatrice was still tender to the touch. The right pupil was dilated, the iris tremulous, the humours glaucomatous, the sclerótica and conjunctiva slightly injected with blood, and she had violent hemicrania. She could, with the affected eye, still distinguish the fingers and other large objects. Pulse 78; much thirst; bowels bound.

On the admission, then, of this patient, there was no appearance of dislocation of the lens. There was amaurosis, and, from the tremulousness of the iris, there was strong reason to suspect a dissolved state of the vitreous humour. I took the opportunity to remark to the students, that this was one of that class of cases which are apt to be mistaken for examples of sympathetic amaurosis, arising from an injury of some of the branches of the fifth pair. She had received a cut above the eyebrow, and, had she not been conscious that her eye was struck as well as her brow, we might have been led to suppose, perhaps, that the cut on the brow

was the cause of the failure of sight. I believe that many, perhaps most, of the cases set down as examples of sympathetic amaurosis, originating in injury of the branches of the fifth pair, have actually been cases in which the eye, as well as the edge of the orbit, had been struck, and the amaurosis, in fact, direct, and not at all sympathetic.

This patient was bled at the arm, to the extent of twenty-five ounces; had six grains of calomel and two of opium at bed-time, and next morning a dose of sulphate of magnesia. On the 9th, the hemicrania was much relieved. She was ordered a pill of two grains of calomel and one of opium every night. On the 10th, she told us that the pain had returned in the afternoon of the 9th, and that it still continued very severe. The conjunctiva and sclerótica we found more inflamed. She was cupped on the right temple, and ordered to take two of the pills at bed-time. The pain was relieved by the cupping. On the 12th the salts were repeated. On the 13th the pain continued easier, and the redness was less. On the 14th, she told us that the pain had set in again on the afternoon of the 13th, and had continued severe till about eight in the evening, when it ceased, and she found that her vision had become much better than it was the day before. At the visit, we found the eye free from pain, and she saw so much better as to be able to distinguish one individual from another. The tremulousness of the iris was not so observable, but the pupil was more dilated. The lens had, from the previous day, become moveable, and was seen, of a glaucomatous appearance, bobbing about, at a considerably greater distance than natural, behind the pupil, on every motion of the head. The upper part of the dilated pupil was clearer than the rest, the lens being partially sunk.

This, then, was a case of displacement of the lens, although it still remained behind the iris. This dislocation, however, we may call *secondary*, as it did not result immediately from the injury, but from the vitreous humour undergoing a farther degree of dissolution than it had done at the patient's admission, a month after the injury.

It must not be supposed that these five cases illustrate all the varieties of dislocation of the lens. That in which the lens passes, through a rupture of the

choroid and sclerotica, so that it is under the conjunctiva in the sixth; and several other varieties might be still mentioned.

Glaucomatous Cataract.

The case which I have first related (that of Long) is interesting in another point of view—it illustrates the nature of glaucoma. I have mentioned that the uninjured eye was glaucomatous. It presented a light greenish opacity, apparently seated in the posterior part of the lens. It is extremely probable that the right eye was in the same glaucomatous state before the accident.

The changes which I have met with in examining glaucomatous eyes after death, are the following:—The lens of an amber colour; the vitreous membrane dissolved; the retina destitute of limbus luteus and foramen centrale; and the choroid deprived of its pigment. Upon this combination of changes I have been led to conclude that the symptoms in glaucoma depend.

In Long's case we had a good opportunity of ascertaining the state of the lens in this disease. The circumferential portion was exactly of the colour and transparency of a bit of common amber. When the lens was held up to the light, its central portion appeared of a deep amber colour, inclining to reddish-brown. On dividing the lens into halves, by a section perpendicular to its surfaces, it was evident that it was the posterior lamellæ which were chiefly affected with the reddish-brown discoloration. There was no appearance of the whitish opacity constituting common lenticular cataract; but the section displayed a want of lustre at the reddish-brown part, as if it were beginning to suffer desiccation, while the light amber part was moist, shining, and pellucid.

The patient with glaucoma sees ill, partly from the retina being unsound, partly from the choroid being unable to absorb the rays of light, partly from the light not being freely transmitted by the central dark-coloured portion of the lens; but still he sees, and sees for many years after the glaucoma has become observable, a sufficient quantity of light for the perception of objects being transmitted through the circumferential portion of the lens.

Glasgow, September 26, 1831.

CASE OF GANGRENE OF THE LEG

OCCURRING IN MEASLES:

Amputation—Recovery.

Communicated by JOHN PAUL, M.D.

SAMUEL CLARKE, 21 years of age, was admitted into Gray's Hospital, under my care, on the evening of the 4th of July 1831, with the leg, from the knee downwards, in an entire state of sphacelus. From the account given of him, it appeared that he had been taken ill of measles on the 17th of May, till which time he had enjoyed perfect health, was active in his habits, and without any vice of constitution; that the fever, preparatory to the appearance of the rash, had run very high, and that the rash had only appeared and disappeared for about eighteen hours, never coming out in the usual manner. That on the 29th of May he was seized with a most acute pain near the junction of the tendon and body of the gastrocnemius muscle, the fever continuing all the while with great severity, accompanied with delirium; that along with this pain he complained of a sense of coldness in the leg and foot, but more particularly in the sole of the foot; and that black spots, with vesications, appeared on the leg on the third day from the seizure of the pain; and on the sixth day the line of separation began, when there was a good deal of swelling in the leg and about the knee. Measles were raging epidemically at the time, in a mild form, and several members of Clarke's family had taken them.

He had not had the benefit of medical advice till gangrene was considerably advanced.

On his admission, it was found that ulcerative absorption had made great progress in separating the mortified limb; the line of demarcation appeared to be passing through the knee-joint. The skin, cellular membrane, and fascia round the joint, over the upper part of the tibia, and upon the calf of the leg, were removed; the ham-string muscles were also divided, and some portion of the capsular ligament laid open. The heads of the gastrocnemius, popliteus, and plantaris, together with the blood-vessels and nerves in the ham, remained undivided, as well as the crucial ligaments and ligament of the patella. On

the living side of the line of demarcation, the edges of the integuments were tumid, hot, and presented some appearance of granulations. The articular cartilages of the condyles of the femur were thickened and partly detached; the bone underneath was soft, spongy, and porous. All below the line of demarcation was black; every thing which constitutes vitality was totally annihilated. The integuments of the leg were dry, shrivelled, and adherent to the muscles. From the ulcerated excavations around the knee there was a profuse ichorous discharge; the fœtor was horribly offensive; in the ham there was a sinus running up along the bone for about two inches; the thigh was a good deal swelled. There was at this time no hiccough, no delirium, yet the powers of life were reduced to the very lowest state of existence, but he was cheered at the prospect of something being now done to save him; he was firm, resolute, and anxious to have the limb removed. In his face there was a circumscribed hectic flush, and his pulse was upwards of 145. In this case the question of practice evidently resolved itself into two considerations, namely, either to rely on the resources of nature, giving her at the same time all due assistance, or without delay to free the system of the local irritation by amputating the limb above the knee-joint. Adopting the first alternative rather than the latter was, in my opinion, subjecting the patient to the greater hazard; because whilst the system was labouring under the highest possible degree of irritative typhoid fever, the cause of irritation was allowed to continue in full operation, the patient in the meantime running the greatest risk of losing his life before separation would take place; and if the undivided parts at the line of separation were cut through by art, the immense surface then to be dealt with, and the profuse suppuration that must have ensued, as well as exfoliations from the femur, with the attendant febrile disturbance, were, under all the existing circumstances, matters fraught with no ordinary danger; whereas the latter alternative not only relieved the system at once of the offending cause locally, but removed from the patient's sight a spectacle most appalling to his feelings, and so offensive to his sense of smell that it could not fail to act injuriously through the medium of the

olfactory nerves. It might be objected to the operation, that the patient in his enfeebled state would not rally from the shock of it and the consequent loss of blood; and that it was uncalled for, nature being adequate to accomplish the process of separation. The loss of blood at this stage of gangrene was, without doubt, dangerous in the extreme, and to be most scrupulously guarded against; but independently of this, any apprehension of danger from the shock of the operation itself, if expeditiously done, appeared to be groundless. That nature would throw off the limb there was no doubt, provided the patient lived long enough, but that was the question, and a very difficult one it was to answer. From the views, then, which I took of the case, there was no doubt on my mind, and I think it will be conceded, that the comparative chance of safety for the patient was much greater by amputation above the knee than trusting to the process of natural amputation, whether aided or not; and such procedure is, if I am not greatly mistaken, in accordance with the most approved principles of surgery.

Having decided on the propriety of amputation above the knee, it was performed by the circular operation, after allowing the patient a few hours of rest. I preferred in the present instance the circular to the flap operation, on account of less surface being exposed, as I entertained some apprehension of union not taking place kindly; but in this I was mistaken, for the patient at the end of three weeks was able to be on crutches, so well did the stump unite, and so rapidly did his general health improve, no untoward symptom having occurred farther than a slight disposition to diarrhœa. The femoral artery and vein were observed to be plugged up with coagulated blood, which in the artery evidently extended high up, as all traces of pulsation were lost a few inches below the groin. The vessels which I had to secure were unusually numerous, large in size, and highly active, so that the profunda and its branches must have been prodigiously enlarged, as well as the anastomosing communications, with the sciatic and gluteal arteries. In this condition of the blood-vessels was displayed a beautiful and wonderful provision of nature; but in her operations intelligent design can seldom fail to be seen, though

never more unequivocally apparent than in the present instance. I have mentioned that the blood was coagulated in the femoral artery, and nearly as high as where the profunda is given off, and the reason of this is at once obvious, because by this means the supply of blood to the leg through the principal vessel was not only cut off, but through every anastomosing channel, the muscular branches of the femoral artery below the point of coagulation being rendered useless; and in this manner the danger of hæmorrhage was effectually guarded against. Nothing, indeed, could be more grand than the adaptation of means here employed to prevent hæmorrhage, in the event of natural amputation taking place; that to maintain the supply of blood to the thigh was equally so; for, as already mentioned, the profunda and its branches were so greatly enlarged that the circulation in the thigh was energetically kept up, and that by vessels not carrying any blood beyond the knee, unless we take into account the minute anastomosis of the extreme branches of the profunda, with recurrent branches from the arteries of the leg.

It would not now be uninteresting to inquire into the causes which produced this gangrenous affection of the leg, if there was any likelihood of arriving at accurate conclusions; but little, I am afraid, can be advanced beyond speculation, which in every inquiry after truth is very unsatisfactory. Gangrene in a patient so young as Clarke, to the same extent, and under the same modifications, is remarkably rare. That it depended on constitutional causes there cannot, I think, be any reasonable doubt, and most likely was attributable to the rash not coming out; for in eruptive complaints it is thought that the specific virus on which they depend is eliminated from the body by the rash appearing for a definite time: and when it does not come out, the virus being in that case locked up, as it were, in the system, an aggravated form of fever is kept up, nervous power is diminished, and gangrene, as in the case under consideration, may ensue. Eruptive fevers, too, predispose the system to gangrene, as we see exemplified in a blistered surface in measles, not unfrequently becoming gangrenous. The occurrence of gangrene in the throat in scarlet fever proves the same thing; and as this

affection of the throat is greatest when there is the least rash on the skin, it naturally follows that it must be through the medium of the rash that the morbid matter is thrown off.

Elgin, Sept. 23d, 1831.

PREMATURE LABOUR.

To the Editor of the London Medical Gazette.

SIR,

IN a case of premature labour, brought on by puncturing the membranes, which I communicated to you some months since, and which you did me the favour to publish in the Gazette, I alluded to a previous instance, in which the same operation had been performed by Mr. Day, with equally good success. In both cases there existed a large projection of the sacrum, which so narrowed the antero-posterior diameter of the pelvic brim, that it was considered impossible for a child of ordinary size, at the natural period of gestation, to be born entire.

The latter of these women, having become again pregnant, was earnestly desirous that the means which had formerly saved her so much suffering, as well as preserved the life of her infant, should once more be had recourse to. This was done by Dr. Day, on the 22d ult. at which time she was about thirty-four or thirty-five weeks advanced in pregnancy. Thirty hours after the membranes had been punctured, labour pains came on, and she was soon delivered of a living child.

Those who have had the misfortune to be engaged in cases where, after waiting for hours, perhaps for days, in the most dreadful perplexity—after beholding the mother's strength gradually sapped by violent, yet ineffectual, pains, it has in the end been found necessary to perform embryotomy; a measure to which not even its necessity can reconcile a feeling mind—will be able to appreciate the advantage of this operation, by which we have it in our power, without suffering to either party, to preserve the life both of the mother and of the child.—I am, sir,

Your obedient servant,

JOHN M'DIVITT.

Regworth, September 26, 1831.

ON THE
JATROPHA CURCAS (THE TUVA TREE
OF THE PHILIPPINE ISLANDS),

AND ON

The Medicinal Properties of its Seeds, &c.

By GEORGE BENNETT, Esq.

Corr. Mem. of the Medico-Botanical Society of
London, &c. &c.

[With an Engraving.]

Jatropha Curcas.

Natural family Euphorbiaceæ.
Class, Monoccia. Order, Monadelphæa.

Generic Character.

Masculi. Calyx nullus seu pentaphyllus.
Cor. monopetala infundibuliformis. Stamina, 10: alterna breviora.
Feminei. Calyx nullus. Corolla pentapetala, patens. Styli. 3 bifidi. Caps. trilocularis. Sem. 1.

Specific Character.

Jatropha foliis cordatis angulatis.—*L. Hort. Cliff.* 445.

Jatropha. Assurgens, ficus folio, flore herbaceo.—*Brown, Nat. Hist. of Jamaica.*
Ricinus ficus folio, flore pentapetalo, &c.—*Sloan, Cat.* 40.

Flos calyce et corolla pentapetala utrisque. Stamina decem. Fructus carnosus, globosus, nec angulatus.—*Willdenow Species Plantarum, Vol. 4, page 561.*

THIS tree is found abundantly at the Philippine Islands, where it is named Tuva; at Ceylon, where it is named Rata-endaru; in the East and West Indies; and, indeed, in all tropical countries. It is usually cultivated for fences, &c. being a tree of rapid growth, and readily propagated by cuttings. At the Philippine Islands, (as well as in India and the Polynesian Islands) the Dap-dap, or Erythrina corollodendron, which bears a profusion of brilliant scarlet flowers, is used for a similar purpose. The Tuva tree is branchy, but does not attain a greater height than from ten to fifteen feet, and is of small circumference; its wood, being of a very soft quality, is useless except as fire-wood.

Similar to all the euphorbiaceæ family, it contains a milky, acrid, glutinous juice, which, when dropped on white linen, produces an indelible stain,

which is at first of a light blue or bluish green colour, but which, after being washed, changes to a permanent dark brown colour; it might, consequently, be employed as a marking ink.

The fruit is globular and fleshy, containing three seeds in distinct cells, and grows in clusters of from four to six; when immature it is of a green colour, which changes to yellow when ripening, and becomes black when quite mature. The seeds are oblong, and of a black colour; the husk being removed, a white kernel remains, which contains much oil, and has an agreeable taste.

The leaves and seeds of this tree are used medicinally by the natives of the Philippine Islands; the former being rubbed over with slaked lime, are used as an external application for headaches, &c.; but as I have observed the leaves of other trees used for a similar purpose, the benefit of their application is probably to be attributed merely to the sensation of coolness they impart in common with other leaves, and which is so agreeable when there is much determination of blood to the head.

The seeds are used as an aperient, but they also possess an emetic property; they do not act speedily as an emetic, an interval of from an hour to an hour and a half elapsing previous to actual vomiting taking place; a nausea, however, is felt soon after taking the seeds, attended by an unpleasant burning sensation in the stomach and bowels, and in some instances, also, in the throat. This emetic property is considered to exist in greater power in the embryo; the husk, and thin membranaceous covering of the kernel, does not contain it, as no difference is perceived after their removal. The modus operandi of this remedy being mild, and the seeds of an agreeable sweetish taste, it would form a pleasant medicine to administer, could its emetic property be separated.

Respecting the active principles contained in the seed, it appears from a chemical analysis by Pelletier and Caventon, (in the Journal de Pharmacie, 1818, No. 7, et Essai anal. sur la graine du médecin cathartique) to contain, besides other principles, an oil and a peculiar acid.

The albumen seems mild; the embryo highly active, which is to be attributed to a volatile principle, as in many of the euphorbiaceæ. Piso says, that

three or four seeds eaten, purge, and violently, if the interior membrane (embryo) is not removed, and therefore it should be always taken away;" and again, "that the nuts should be roasted, that they might operate more gently."

It is stated by Adrien Jussieu *, that "the emetic effects are produced either by the oil or farina, when taken internally or applied externally, but much more speedily from the oil, and still more violently by the acid, to which the strength of the oil appears attributable, for when made into a saponaceous substance its effect is lost."

The seeds are collected by the natives of the Philippine Islands for the purpose of expressing the oil, which they use for burning in their lamps, as well as for medicinal purposes.

The seeds are used by the native doctors at the Philippine Islands, and from one resident at the village of St. Roque, near Cavité, I collected the mode of administration, dose, &c. He described them as being an excellent purgative, and he gave them in doses of from one to four, (the latter number being seldom exceeded) according to the age of the patient; one for the age of three or four years; two at ten or twelve; three at fifteen or eighteen years; and four as a full dose for an adult. The effects which result from an overdose are violent vomiting, purging, a burning sensation in the stomach and bowels, with a determination of blood to the head. The only antidote used by the native practitioners is repeated draughts of cold water; warm water, they observe, would be very injurious. When administered, the kernels of the nuts are extracted from their shells, and given in that form; but more usually by pounding them in a mortar, to which water is added, and after being well mixed together, it is strained, and given as a draught to the patient. It operates in a few hours after it has been taken. It was said to be an excellent purgative in venereal cases.

One afternoon, whilst gathering some of the seeds of this tree from a fence which surrounded a native dwelling in the vicinity of Cavité, I was accosted by a little Indian girl, of about eight years

of age, but possessing a large share of "secretiveness." She exercised that portion of her cerebrum in endeavouring to persuade me that the seeds I was collecting were very agreeable to eat. "Do taste them, señor, they are so very nice." I requested, as they were so agreeable, that she would eat one. She refused with a sly look, alleging as a reason, "that she had eaten so many yesterday, that she could eat no more this day." I at last told her that I was aware of the effects of the seeds, and was certain, that had she eaten so many yesterday, she would have been too ill to have eaten any this day. She laughed when she found her trickery discovered, and said it was true, that if she eat them she would have vomiting, purging, and perhaps die; but still, if I wished to know whether her statement was correct, I had better eat some; saying this she scampered away, leaving me to collect my specimens, and try the effects if I pleased.

I occasionally administered these seeds, but always found their effects (although in a recent state) very irregular among Europeans, some requiring a dose of from six to eight, others requiring only the usual dose of four; but in all an uneasy burning sensation in the bowels, with nausea and vomiting, followed. I took myself four of the seeds, and experienced a very unpleasant burning sensation in the stomach and bowels, with nausea, which after an interval of nearly two hours, terminated in vomiting; their purgative effects followed soon afterwards, and operated mildly; the sickness had then nearly passed away, but the burning sensation continued for some time longer.

Labillardiere states, that at Amboyna "most of the gardens were surrounded by shrubs, among which I remarked the *Jatropha curcas*, the plants of which grew so close together as to form good palisades: its seeds have the taste of a filbert, and are far from disagreeable. The natives cautioned us, that although eaten even in small quantities, they occasioned a *great drowsiness*; they were not aware that the narcotic quality of this fruit is seated in the part known to botanists by the name of the *embryo*. I had the satisfaction of informing them that after taking this out they might

* De Euphorbiacearum Generibus Medicisque, garumdem viribus tentamen, pages 93, 94, 410.

eat the kernel in perfect safety*." This is not a correct statement: the seeds of the tree are not possessed of any narcotic property. The effects intimated by the natives must be that illness would be produced by eating them: the active purgative and emetic principles being more powerfully in the embryo than in other portions of the seed, would, of course, by the removal of the embryo, be materially diminished, if not in the greatest degree lost.

At Chanti, on the coast of Sumatra, (which place I visited on the 29th of

November, 1830) I observed the fences formed of this tree, which was named *jarah* by the Malays. The castor-oil tree (*ricinus communis*) is named by them *miniak jarah*; and by the Javanese, *linga jarah*. Is the word *jarah* applied by the Malays to all seeds which have a purgative quality?

The accompanying drawing was made from a recently gathered specimen at Manilla. (Island of Luçonia).

(a) Represents a seed detached from the capsule.

In Hughes's Natural History of Barbadoes, it is named the physic-nut tree, (*ricinoides*); and he observes on the fruit, that its "outward tegument is green and husky; this being peeled off, discovers the nut, whose shell is black, and easily cracked; this contains an

almond-like kernel, divided into two parts; between this separation lie two milk-white, thin, membranaceous leaves, easily separable from each other, (embryo). These have not only a bare resemblance to perfect leaves, but have, in particular, every part of the stalk, the middle rib, and transverse ones, as visible as any leaf whatever. The kernel is

* Labillardiere's Voyage in Search of Perouse, vol. i. page 264, 8vo, edit.

not only edible, but has a delicious almond taste." He also observes, that "it is the common opinion, that the *purgative* or *emetic* quality lies in the two membranaceous leaves (embryo) that separate the kernel into two partitions; but this (he further observes) is a mistake, for I have, as well as others, tried it both ways, and its physical effects were with or without these, always the same." "The leaves and tender buds emit a milky juice, which, either by exposure to the sun, or being rubbed on the palm of the hand, turns to the consistence of a salve, which is looked upon to be very good to heal any green wound. The nut likewise, when ripe, pounded, and boiled, will yield a considerable quantity of oil. A spoonful of this, swallowed whilst fresh, is considered a good purge to abate swellings in dropsical disorders*."

Brown observes (Natural History of Jamaica, folio, 1789, page 348) on this tree, that "it is very common in all the sugar colonies, and cultivated frequently in inclosures. It grows sometimes to the height of seven or eight feet, or better, but dies after a few years. The leaves are much used in resolute baths and fomentations, and the seeds sometimes as a purgative; but they operate very violently, and therefore are now but little used."

Some croton oil which I administered from a ship's medicine chest had similar emetic effects, attended by a burning sensation in the stomach, bowels, &c. as the Tuva seeds. From that circumstance it may be inferred that an adulteration had been made with oil extracted from the seeds of the *Jatropha curcas*, which is, I believe, a frequent fraud in the croton oil of commerce.

London, Sept. 18, 1831.

POWER OF THE COMPANY OF APOTHECARIES OVER THE MEMBERS OF THE COLLEGE OF SURGEONS, &c.

To the Editor of the London Medical Gazette.

SIR,

CAN you inform your readers, who are interested in the subject, whether the act of 1825, 6 Geo. IV. which was

passed for *one year*, in order to amend the Apothecaries' act of 1815, has been re-enacted, or whether any provisions have been made relative to two points which that act contained?

1. Have the Apothecaries the power of refusing examination to any student who has not been apprenticed to one of their own body for five years? The act I allude to gave them power to examine students "who shall produce proof of having served an apprenticeship of not less than five years, to a member of the Royal College of Surgeons in London, or Edinburgh, or Dublin—or to a surgeon in his Majesty's army or navy; together with proof to the satisfaction of the Court of Examiners, of a sufficient medical education, and of good moral conduct; in like manner as by the said act is provided with regard to persons who have served an apprenticeship of not less than five years to an apothecary."

If the amendment of this act is not in force at the present time, it is unjust to a large body of men, as a great proportion of the general practitioners throughout the country have been in the army or navy, and have not been licensed by the Apothecaries, and all their apprentices, as well as those of the pure surgeons, are, by the act of 1825, excluded from examination, however competent they may be.

2. The same act of 1825, by the fourth clause, provided that all who held at that time, or should thereafter hold, commissions or warrants as surgeon, or assistant-surgeon, in his Majesty's navy, or as surgeon, or assistant-surgeon, or apothecary, in his Majesty's army, or as surgeon or assistant-surgeon in the service of the Honourable the East India Company, should be entitled to practise as apothecaries in any part of England or Wales, without having undergone any examination or received any certificate from the company of Apothecaries. Are any of these surgeons, after the excellent examinations they undergo at their respective Boards, obliged again to submit to examination before they can practise? Or do the surgeons in the army or navy receive as a courtesy what they did and ought to enjoy as a right, while the Company refuse even this courtesy to the surgeons in the East India Company's service?

These are points of some importance

* The Natural History of Barbadoes, by Rev. G. Hughes, folio, 1750, page 115.

to many of the members of the College, relative to which I know that many of your readers would be glad to receive information.

I am, Sir,
Your obedient servant,
A MEMBER OF THE COLLEGE OF
SURGEONS.

Oct. 5, 1831.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Reports of Medical Cases, selected with a view of illustrating the Symptoms and Cure of Diseases by a Reference to Morbid Anatomy. By RICHARD BRIGHT, M.D. F.R.S. &c. Lecturer on the Practice of Medicine, and one of the Physicians to Guy's Hospital. Vols. II. and III. £9. 9s.

THE great expense of these volumes will unavoidably preclude them from being very generally purchased, and for a knowledge of their valuable contents our professional brethren will be mainly dependent on the medical journals. In some of our early numbers we laid before our readers an account of Dr. Bright's first volume, and as those now before us fully maintain the character of their predecessor, it may be supposed that we are anxious to give an equally faithful digest of their contents. For this purpose we shall take up, in a succession of articles, the subjects of the second and third volumes, though not perhaps exactly in the order of their occurrence. We may remark, by the way, that our objection to the plates in the first volume, "that the author and the artists, in their anxiety to preserve the full force of that vivid and varied colouring which nature presents, have in one or two instances gone too far*" is here done away—the science of the anatomist, and the cunning of the draftsman, having united to produce a fidelity and chastened brilliancy in the delineations which are not exceeded in any plates which we have ever seen.

The arrangement is in some degree different in the present volumes from that adopted in the former; for in-

stance, instead of bringing together dissertations on particular diseases of different organs, the derangements of one individual organ are grouped together. Thus the second volume is almost entirely given to the brain and nervous system, the diseases of which are considered under the heads of INFLAMMATION, PRESSURE, and IRRITATION, according to the prevalent morbid condition; while with the second of these *Concussion* is associated; and with the third, a state to which the author gives the name of *Inanition*. The symptoms indicative of these several states of disease are thus described:—

"The symptoms of inflammation of the brain and its membranes are a general febrile condition, a quick and often a hard pulse, pain in the head, and sometimes in the limbs, sickness, convulsion, injected conjunctiva; sometimes simple confusion of ideas, at other times active delirium, with a quick though frequently faulty perception, sometimes intolerance of light and sound, sometimes a careless or wild contempt of all external objects or all ordinary sources of excitement; and all these symptoms suffer considerable modifications both from the situation and acuteness of the inflammation, and from the stage of its progress and the consequent changes which the parts are undergoing.

"The symptoms indicating the state I have designated pressure, are loss of voluntary power, from the most momentary, trivial, and partial, to the most fixed, general, and complete paralysis; and so likewise all degrees of depraved and impaired sensation, dullness of intellect, failure of memory, oppressed circulation, coma, sopor, apoplexy: but these symptoms of interrupted function probably arise likewise from other causes besides actual pressure, which it is not easy to appreciate.

"The symptoms of concussion are, loss of consciousness, sickness, headache; pulse irritable, often quick and irregular, or easily excited; pupils unequally dilated and contracted; and sometimes convulsion and delirium, or idiocy.

"The symptoms more particularly marking irritation in the brain are restlessness, discontent, screaming, agitation of manner, convulsion, and a pulse generally frequent, but variable both in frequency and strength.

"The general symptoms of inanition

* Gazette, vol. I. page 127.

are a pallid countenance, flaccid skin, and weak circulation, as marked by a feeble pulse with or without sharpness in the beat. The symptoms more immediately affecting the head and nervous system are, dull pain, sense of noise, indistinct vision, despondency of mind, irritability, wandering delirium, epileptic syncope, and coma.

"1. Inflammation of the brain and its membranes may be idiopathic, or the result of the febrile action excited in the system, as in fevers, whether continued, remittent, intermittent, or exanthematous, and in some inflammatory affections of other parts, as of the different viscera of the abdomen; or it may arise from the extension of inflammation, as in erysipelas, and in cases where inflammation has been set up within the cavity of the ear, and in cases of diseased scalp or cranium; or it may depend on some other diseased action going on in the system, and thus be considered metastatic, as in gout or rheumatism; or, again, it may be excited by external injury from violence.

"The appearances which result where the membranes chiefly suffer, and death takes place early, are undue vascularity in various degrees, unusual dryness of the membranes, and rather a deficiency of fluid in the ventricles, effusion of serum, often assuming a gelatinous appearance from being held in the fine tissue of the pia mater, unnatural adhesions between the membranes, and between these and the brain, the deposit of fibrin forming adventitious membranes, and the formation of pus, more particularly where the membranes have suffered from external violence. Inflammation of the substance of the brain may present increased vascularity pervading the whole or a part, and unusual adhesions between the brain and its membranes, or may go on to suppuration and the formation of ulcer or of abscess, and occasionally destroys the consistency of the brain without actual suppuration. But inflammation both of the brain and of its membranes will frequently destroy life by sudden exhaustion, leaving very doubtful proofs of the inflammatory nature of the disease.

II. Pressure of the brain may depend, and that even in its most urgent and sometimes fatal forms, simply on the state of the circulation within the head, as in cases of venous congestion giving rise to head-ache, vertigo, lethar-

gy, and even apoplexy. Disordered circulation may depend upon the quantity and the mode of distribution of the blood; which are the only derangements that can immediately produce pressure, and this deranged circulation may arise from local causes, or from some more general cause, as disease in the heart or the lungs: but the circulation may also be disordered in another way, by the morbid condition of the circulating fluid;—thus in cases of jaundice, diabetes, anasarca with renal affection, and ischuria renalis, and bronchitis, and in asphyxia, there is some reason to believe that, independently of the pressure which the brain suffers by the retarded circulation, the quality of the blood acting not alone on the brain, but on the nerves of the whole body, adds to its injurious effects; and it is possible that the peculiar loss of power consequent upon the external as well as the internal use of lead, may depend on a condition of the brain in which congestion is combined with a diminution of nervous energy, from the immediate sedative action of the lead.

"2. The rupture of vessels in the brain or spinal cord, and consequent effusion of blood, as in cases where single large vessels are ruptured, sometimes in consequence of disease, as aneurisms or ulceration; sometimes from accident; and in cases where several small vessels are ruptured, throwing out blood separately, and either coalescing into one clot, or forming many small lodgments of blood.

"3. Effusion of serum without obvious inflammation, as in those cases of fatal apoplexy where no other visible evidence of disease remains, but serum effused either into the ventricles or under the membranes of the brain: so likewise in chronic hydrocephalus, and in cases of great debility, as phthisis, or other diseases where the free transmission of blood through the lungs is prevented, as in cases of death from hanging or from exposure to intense cold. Serum is occasionally found in considerable quantity under the arachnoid, when slight drowsiness and wandering of intellect have been the only symptoms during life.

"4. The various results of common inflammation, as effusion of serum or pus, or the thickening of membranes, or the softening of portions of the brain, which acts by allowing pressure

to be made by one part falling unsupported on another, or possibly only produces symptoms of pressure, by interrupting the nervous communication.

"5. The results of peculiar diseased actions; as scrofula, carcinoma, fungous disease, melanosis, and osseous deposits, either in the cranium, on the membranes, or in the substance of the brain: to which may be added certain organic changes, producing partial or general induration, without being referable to any specific action. But in all these the symptoms of pressure are usually combined with those of irritation.

"III. With regard to concussion, the causes producing it appear so decidedly mechanical, that there is much reason to believe the symptoms depend upon the mechanical derangement. Frequently this is so slight, that the vessels of the brain being previously healthy, a few hours or days repair the injury; in other cases it is not so, and the lacerated fibres and vessels mark the injury after death. Perhaps the ultimate morbid condition on which the symptoms of concussion depend, arises from interruption to the circulation and to the natural communication between the fibres and particles composing the nervous tissue.

"IV. Irritation of the brain or its membranes may arise from disease within the cranium or from disease in distant parts; and although the irritating cause may frequently be the subject of anatomical demonstration, and the results of continued irritation may sometimes be shewn, yet the existence of this condition must chiefly, if not altogether, be traced in the symptoms which it produces.

"First: in some instances the irritation arises from causes within the cranium; as,

"1. The paroxysm in certain forms of mania, where the irritation appears to be connected with a peculiar and inexplicable irritability of the nervous structure itself; frequently, however, depending for the temporary increase of the habitually morbid state upon increased circulation, and in such cases giving evidence of the fact by the appearance of vascularity after death.

"2. Other kinds of fixed mania depending on the derangement of the mental functions from original or acquired conditions of the brain, respecting which we are quite ignorant, but which

are occasionally connected with appreciated organic changes.

"3. Paroxysms of epilepsy, chorea, or neuralgia, dependent on disorganization acting independently of pressure, and without producing the symptoms of that condition. As in cases where the disorganization has been slow, the brain having gradually acquired unusual hardness or softness, or become the seat of some tumor or morbid growth; each paroxysm in these cases generally depending on some change in the state of circulation, and sometimes on distant irritation, when the mischief within the brain may be considered as little more than a predisposing cause.

"4. Headaches, and various nervous feelings connected with a diseased condition of the vessels of the brain, as in some of the premonitory symptoms of apoplexy.

"Secondly: irritation of the brain may depend upon remote morbid agencies, or diseases going on in some distant part; as,

"1. The delirium in certain states and periods of fever from irritation of the abdominal viscera; and it is not quite obvious whether the delirium attendant on some acute cases of inflammatory disease, as peritonitis, should be classed with these or with the truly inflammatory affections; it probably commences in simple irritation, but inflammation is afterwards set up; and the same may be said of those cases of delirium, arising when the functions of the liver have been greatly deranged.

"2. Epilepsy and convulsion coming on at the commencement of eruptive and other fevers, or in cases of suppressed gout.

"3. Epilepsy and convulsion from worms or other irritation in the alimentary canal, or from teething.

"4. Hysteria from uterine sympathy.

"5. Choreia from uterine or other irritation.

"6. The peculiar tremulous and spasmodic action produced by inhaling the fumes of mercury.

"7. Tetanus and hydrophobia, possibly from the irritation of the nerves of the injured part.

"8. The effects of certain poisons, such as strychnia, which, according to the late ingenious experiments of Dr. Addison and Mr. Morgan, appear to act through the medium of the nervous system.

“9. To this division may likewise be referred those various affections of the head, as well as those mental aberrations which depend on the state of the stomach, sometimes shewing themselves in confirmed hypochondriasis.

“V. Inanition or deficient circulation is a very powerful cause of many derangements in which the brain and nervous system bear a prominent part: it shews itself in that general want of power which depends on an insufficient supply of nourishing and stimulating blood to the brain. It may arise from excessive depletion; in which case it may be but a temporary effect, having amongst its symptoms, intense headache, a sense of singing in the ears, deafness, confused vision, or total blindness, syncope and convulsion. If depletion have been carried further, or very frequently repeated, the effects may be more permanent, marked by paleness of countenance, by unusual effort of the heart, throbbing at the temples, headache, confirmed lassitude, despondency, and all this occasionally terminating in convulsion or coma. The same state may arise from insufficient nourishment, or from a deficiency in the supply of wholesome air or exercise. It may also arise from internal causes weakening the power of generating blood, and giving birth to all the symptoms connected with chlorosis and *anæmia*.

“Examination after death proves the remarkable deficiency of red particles which has existed in the blood during life; and the effused serous fluid which is discovered both in the ventricles and under the arachnoid, often affords a satisfactory explanation of the symptoms of pressure which have immediately preceded death.”

INFLAMMATION.

The first section is devoted to inflammation, and contains illustrations of the various forms of *arachnitis*, *phrenitis*, and of softening of the brain. In the present notice our space will not admit of our attempting more than to illustrate

Arachnitis and Delirium Tremens.

Of late years attempts have been made to carry diagnosis to a pitch of excellence which it had not previously attained; and it cannot be denied that the improvements in this respect have been prodigious. Perhaps, however,

though much has been attempted, less comparatively has been accomplished with regard to the head than other regions of the body, and those who study symptoms in the sick chamber, and morbid anatomy in the dead house, will be the most ready to suspect that the attempt to fix with mathematical precision the exact and individual spot in which inflammation has existed, or fluid will be found within the cranium, is but among the refinements of the enthusiast. While Dr. Bright admits that the symptoms are to a considerable extent modified by the situation as well as degree of inflammation, and from the precise changes which the part is undergoing, he attempts no fine drawn, or bewildering subdivisions, but gives his description of inflammation of the contents of the cranium generally.

The manner in which cerebral inflammation makes its attack varies much in different instances, being sometimes sudden, and very speedily running its fatal course; at other times being slow and gradual, stealing on with a stealthy and unsuspected pace. Various cases are given in illustration, but we must confine ourselves to those in which some modification existed, so as to divert attention from the actual seat of disease, or otherwise render them deserving of particular notice.

“Arachnitis, with excessive Irritability, in an intemperate Man.”

“Thomas Surnian, aged 35, was admitted into Guy’s Hospital, November 27, 1827. During the last ten years he has worked at a distillery, and has drunk freely both of porter and spirits. He has always had good health, with the exception of a general tremor in the morning after he has been intoxicated. Five days ago he received a blow on the upper part of the neck, which occasioned only a feeling of stiffness; and as he felt ill on the next day, he took aperient medicine, and rubbed a liniment on his neck. After this time he had only a slight headache, and appeared to be doing very well till the day before his admission, when, without further obvious cause, about three o’clock he became delirious, talking incoherently, but was not violent. At seven o’clock p.m. he was bled in the recumbent posture to a pint and a half, when he became faint; six leeches were applied to his temples; a blister to the nape of his neck; and vinegar as a lotion to his head: since this he has been more quiet, though delirious. At the time of admission there was a general tremor; a hurried man-

ner, constant motion of the eyes; he fancied he saw objects before him, and occasionally picked the bed-clothes; his answers, though quick, appeared rational; a slight flush on the cheeks; no headache. Pulse 98, rather sharp, but very compressible. Skin hot and perspirable. Bowels open the day before.

Hiæbeat Hydrag. Submur. gr. v. statim, et Olei Ricini, ℥ss. post horas quatuor; Applicetur Embrocatio communis capiti raso.

"He became so violent in the afternoon as to require restraint. His bowels were moderately open; and about nine o'clock, having immediately before been singing, he fell suddenly into a state of collapse, and, although stimulants were as freely administered as possible, he died in a quarter of an hour.

"When moving the body on the following morning, a considerable flow of blood from the mouth was observed.

"*Sectio Cadaveris.*—This was performed fifteen hours after death. The sinuses of the dura mater contained much fluid blood. There was a small quantity of serum underneath the arachnoid. The veins of the pia mater were large, as if habitually distended; but the flow of blood which had taken place from the longitudinal sinus on first removing the calvaria, had apparently emptied them. The pia mater peeled off naturally and exposed healthy convolutions; it was a matter of doubt whether the bloody points in the substance of the brain could be considered more than perfectly natural. About two drachms of fluid in the ventricles, and nearly an ounce about the basis of the brain.

"The lower and posterior part of both lungs, especially of the left, presented an appearance as if blood had found its way into the cells, being of a dark red colour, and in some parts having a greenish tinge, and even a putrid odour, which could scarcely be ascribed to decomposition in so short a time after death; some old adhesions on the right side. The heart was very flabby, and there was an ecchymosis on the left ventricle, just below the semilunar valves of the aorta.

"The liver large, of a drab colour, interspersed with yellow mottling. Ducts of gall-bladder pervious, and bile good. Spleen healthy, but adherent to the diaphragm.

"Kidneys, particularly the left, pale and flabby. Intestines generally distended; and an arborescent vascularity on the mucous membrane of the stomach."

This case illustrates that peculiar morbid condition commonly known to us by the name of delirium tremens; wherein the inflammatory action is so modified by constitutional irritability as to render a very guarded, if not apparently contradictory treatment, imperatively ne-

cessary. In the present instance the local injury can scarcely be regarded as sufficient to account for the fatal attack, which was probably entirely dependent on the previous habits of the patient. The extreme irritability, the absence of headache, the weak pulse, and perspiring skin, would seem to have indicated the use of opium, and this we are told was to have been adopted after the bowels were sufficiently opened had it not been for the sudden collapse by which the patient was meantime cut off. This is just the mode in which we have repeatedly seen such cases come to a sudden end, the patients sinking after even a moderate bleeding, and dying in a few hours. The effects of an opposite mode of treatment are strikingly shewn in the following case:—

"*Arachnitis, with excessive Irritability, in an intemperate man.*

"In the year 1823 I was requested to see a gentleman, residing at a distant part of the city, who had unfortunately contracted habits of intemperance, and had become suddenly delirious the day before. Leeches had been applied to his temples; and his delirium, so far from being relieved, seemed to be greatly aggravated, so that he passed the night in most violent agitation, requiring the strength of two or three persons to restrain him; and on one occasion he had nearly leaped out of the window. Such still continued to be his state when the message came to me; but when I arrived two or three hours afterwards, a most striking alteration had taken place; for on his expressing a strong desire in his delirium for a mutton-chop and some porter, the medical man who was attending him thought it not improbable that it might do him good to have some solid food on his stomach, and at once granted his request;—the effect was almost instantaneous. His mind became calm and collected; and when I saw him, little but general nervous agitation and a hurried manner of speaking remained; and a few doses of opium with calomel was all that I saw occasion to recommend. He afterwards told us, that the state of his mind during his delirium was most peculiar; it seemed, as he expressed himself, as if he were two separate persons, for he knew those who were around him, but still he went through a kind of clear connected dream, in which he was tried for murder, and condemned; and when on the point of leaping from the window, it was in his attempt to escape from the officers of justice.

"It is certainly very difficult in a case like this to recognise the existence of any actual inflammation; yet the predisposing causes of this attack, the character it assumed, and the treatment to which it yielded,

bore every mark of being immediately allied to those inflammatory affections, coupled with excessive irritability, of which we are speaking, and which sometimes terminate almost as suddenly in death as this did in recovery."

The consideration of such facts leads to a reasonable doubt as to the nature of this morbid condition being really inflammatory; at the same time it is unquestionably allied to inflammatory affections. In other instances, indeed, a state of irritability is evidently co-existent with acute inflammation within the head. The eighth case, unfortunately too long for extraction, is an example of this kind. A woman, of intemperate habits, had violent delirium, a wild eye, sharp pulse, and furred tongue, but without pain in the head, at least she denied having any. She was bled twice, and the blood was much buffed the first time and partially so the second. Dr. Bright, from the circumstances of the case, feared to employ farther depletion, and therefore gave calomel and hyoseyamus in large doses.

As soon as the mouth got sore, (which was not till she had taken nearly a hundred grains of the latter, and quite that of the former) all her symptoms disappeared.

"A cautious review of the foregoing cases cannot fail to impress upon the mind the very important peculiarities attendant upon inflammation of the membranes of the brain, in all those spontaneous cases which arise so frequently where the nervous irritability has been greatly increased by intemperance or distress of mind. It cannot certainly be laid down as a rule, that in such cases bleeding must never be had recourse to; but that it should be adopted with much caution cannot be doubted, and it should be immediately followed by the administration of opiates combined with calomel. The very early use of tonics, and even stimulants, will in many cases be advisable; and improvement in the diet, more particularly the substitution of some solid food, together with a limited quantity of malt liquor, instead of slops, will be beneficial; and in all cases the strictest attention must be paid to the removal of every source of mental disturbance and excitation; and with this view, all restraint, except such as is absolutely necessary for the safety of the patient and his attendants, should be avoided. The head should be constantly

cooled by evaporating washes, and the atmosphere should be kept as cool and as pure as possible. The calomel, in conjunction with more or less opium or hyoseyamus, according to the degree of irritability, should be continued till the symptoms have completely subsided, or the mouth is affected.

Maingault's Illustrations of the different Amputations performed on the Human Body. Represented by Plates, designed after Nature, with Alterations and Practical Observations. By WILLIAM SANDS COX, Lecturer on Anatomy and Surgery at the Birmingham School of Medicine, and Surgeon to the General Dispensary. Longman and Co. London.

WHEN we look over the delineations of anatomical subjects in times past, (mere caricatures, if published at a moderate price, or if well executed, their price so high as to limit their sale, and therefore their usefulness, to a small number of persons,) and then turn to some of those offered to the public at the present day, combining the advantages of fidelity and cheapness, we must acknowledge the benefit which anatomy has derived from the introduction of lithography. The work before us is intended to facilitate the performance of amputations, not by giving minute or lengthened descriptions, but by "reducing to a small number the general rules to be observed in their performance; by representing the different modes of operating, by lithographic engravings designed after nature, the form and extent of the wounds—the principal points to be observed, and by enumerating every circumstance with the greatest simplicity."

The delineations are so arranged, that the member amputated is placed beside the same in its natural state, with a view to indicate clearly the processes of bone corresponding with the line of the incisions; and the precise point at which the operation should be performed is marked by dotted lines, drawn over the surface, so as to indicate the extent and direction of the incisions. The author remarks, that the perusal of his work will recall to the surgeon the memory of facts which time may have effaced; and the student, without the aid of a teacher, will be able to com-

prehend and perform the different operations in the dissecting-room.

This useful publication has not been merely "done into English," as our fathers used to say. Mr. Cox did not take upon himself the office of a mere translator; he has made alterations and additions wherever they appeared necessary, and with the more confidence as "he has been in the habit of demonstrating them to his surgical class."

The value of the work, in its English garb, is thus very much enhanced; so that we have no hesitation in recommending it to the student and the young surgeon.

MEDICAL GAZETTE.

Saturday, October 8, 1831.

"Licet omnibus, licet etiam mihi, dignitatem *Ar-tis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

THE CONTROVERSY ON THE DECLINE OF SCIENCE IN ENGLAND.

WHEN Mr. Babbage, supported by an able writer in the *Quarterly Review*, undertook, some months ago, to assign the *causes* of the neglected state, the positive decline of science in these kingdoms, we must confess we were considerably dazzled by the splendour, and carried away by the weight, of the great authorities which we found engaged in the inquiry. Mr. Herschel, the highest name we now have in the list of our men of science, seems to have begun the complaint: he grumbled, chiefly indeed about the neglect of certain novel investigations in chemistry. "Who can tell us here (in England)," said he, "any thing about the sulpho-salts; or of the laws of isomorphism? Who among us has verified Thenard's experiments on the oxygenated acids; or Oerstadt's and Berzelius's on the radicals of the earth; or Balard's and

Serullas' on the combinations of brome, &c.?" Hence, by rather a questionable species of argument, he drew sweeping conclusions unfavourable to the state of English science generally, and, what was still more serious, drew after him, into the same conclusions, a number of eminent persons, who all deemed the authority which they followed paramount, and the opinions which he dictated incontrovertible. Mr. Babbage was first in his wake, and put the *argumentum ad verecundiam* so strongly in the work to which we have alluded*, that though "great names were among us," no man could assume to himself the high privilege of playing the champion in his own and his country's behalf. The example of such high authorities, voluntarily coming forward to maintain their own inferiority to their continental brethren, or, perforce of certain modest warnings of acquiescence, remaining silent, though not content under the imputed degradation, had almost the efficacy of an axiom with the public; and the fact of the decline of science amongst us was vulgarly considered to be as unquestionable as are the existence and increase of our national debt. All eyes were directed to the discovery of the *causes* of this supposed fact, and many and ingenious were the immediate antecedents pointed out by distinguished inquirers. Dr. Brewster, who is supposed to have written the article in the *Quarterly Review* to which we drew the attention of our readers soon after it was published, and who, by the identity of opinions expressed in his late biography of Sir Isaac Newton, would seem to warrant that supposition, has summed them up succinctly, under three or four heads; among which we recollect "the ignorance and supineness of government" was one, and the "indirect

* Remarks on the Decline of Science in England.

persecution of our men of science, by their exclusion from all honours of the state," was another. Now it is curious enough, that the defence of our national character, from the disgraceful imputation of the decline of science, has come from a quarter, whence, of all others, it could least have been anticipated :—

“—*Vin prima salutis,*

Quod minime reris, Graia pandetur ab urbe.”

If a prophet were to divine to us, a month ago, that from Holland was to come the first gleam of our redemption from the stigma which was nearly impressed upon us by consent, we would not have believed him—we would have repudiated him as a meddling fool; yet, without being either an *Œdipus* or an idiot, his word might have been taken for good; his veracity would have proved fully borne out, and Mr. Faraday would have come forward to put in lawful bail for him. In short, here is an honest Dutchman come to judgment; and as we have hitherto had an opportunity of stating but one side of the question, chiefly owing to the modesty, or rather the unaccountable want of nationality, which seems to have befallen our men of science on this side of the German Ocean, we shall take leave to hear this learned foreigner's decision, and detail some of its more important points and leading features for our own and our readers' edification.

A pamphlet has recently been published, bearing for its title, “*On the Alleged Decline of Science in England; by a Foreigner.*” It was professedly sent to the press by Mr. Faraday; and we must honestly avow, that our first impression upon its falling into our hands, and even after a hasty first perusal, was, that its ostensible foster-father was its real parent. Nothing so natural, we thought, as for a man like Mr. Faraday, so well acquainted with our intellectual resources, and himself

occupying so distinguished a place among the first chemists of the age, to make use of a little *ruse* of this sort—to throw over himself the modest disguise of a “foreigner”—and to enter the lists boldly against Mr. Babbage, and “all manner of folk.” But our hypothesis, unfortunately, was not doomed to be long lived; the author of such a pamphlet could not long remain concealed. Inquiry was set on foot with unremitting activity; and the foreigner now all as good as “stands confest*.”

The usual course of proceeding in demolishing an antagonist's arguments about matters of facts, is, as is well known, to *remove* the cause, after which the consequence follows, as it naturally should. Our “foreigner” has not deemed so much formality necessary: he comes at the *effectus* at once; and, with extraordinary valour, declares it to be a nonentity, or at best, but a phantom—a breath—a mere assertion. “Before we can follow Mr. Babbage,” says he, “in his long list of complaints, we must pause a moment in the consideration of the assertion, that ‘science is declining in England.’ This harsh sentence, however, admits of several interpretations, and Mr. Babbage has not informed us which is that which he adopts. Is it his opinion that science is stationary in England, whilst it is making rapid strides on the continent? or does he wish to give us to understand that really a retrograde motion takes place in England; and that although, upon the whole, science is more widely diffused at present in England than formerly, there is a lack of scientific men of the first eminence able to be put upon a par with the most renowned foreigners? Mr. Babbage must excuse me for believing, that it is not sufficient thus confidently to assert the inferiority of his own country; he ought, in my opinion at least, to have pointed out dis-

* He is Dr. Moll, we understand, of Utrecht.

tinctly where the inferiority exists. Are only some branches of science affected, or does it spread widely over all the departments of human knowledge? It may be, that England should be found deficient in some particular instance, whilst in others, perhaps, it far surpasses other nations. The scale of merit ought to be carefully handled, to determine to which side the balance is leaning. But if the real meaning of Mr. Babbage, on a question in which the national honour is so deeply involved, is labouring under an obscurity which we have no means to dispel, we may attempt at least to canvass the authority by which he supports his opinion. The names of Sir Humphry Davy and of Mr. Herschel are, of course, of the highest authority; but it would appear rather strange that any one should attempt to couple *those* names with a complaint of a decay of science. This sounds pretty much as if, when speaking of Wellington and Nelson, one would argue on the inferiority of the British army and navy. The mere mentioning of the names of Davy and Herschel would furnish a proof that science *was* flourishing in that country which gave birth to these highly-gifted individuals."

We regret that our space will only permit us to allude to the arguments, whereby he shews that if, as a writer in the *Encyclopædia Metropolitana* asserts, our chemists neglected their chemistry in consequence of Oerstadt's discoveries, it was only a temporary suspension of their labours in one branch of science that took place, in order that they might be directed to another. And what redounds more, in his opinion, to the credit of English chemists is, that *they* took a leading part in these new investigations. Dr. Wollaston and Mr. Faraday made their several discoveries in electro-magnetism; while, amongst the first promoters of that novel branch of

science, we do *not* find Berzelius, Thénard, Gay Lussac, and other great chemists of the continent.

But we must give some of our author's excellent remarks on the alleged want of *efficient patronage* of scientific men in England:—

"Sir Humphry Davy complains of the little interest which noblemen take in science, and of the necessity which compels many persons, inclined to scientific research, to look for other means of sustenance; but both the evils of which Sir Humphry complains do not belong to England alone. Nowhere noblemen care much for science, and pecuniary wants deter many all over Europe from pursuing a scientific career. No great penetration is wanted to see merit struggling with want and poverty in every country in the world; and, perhaps, it might be said, that science has a better chance in England than elsewhere, of securing an honest independence to its possessor. Dr. Wollaston, by his scientific exertions, procured himself that pecuniary supply, without which the greatest genius and the ignorant are alike unable to support themselves. Now, I will tell Mr. Babbage, that in no other country of Europe could Dr. Wollaston, unassisted by kingly favour, have been able to earn by his scientific discoveries, that independence which gave him the necessary leisure to apply all his mental force to the pursuits of science. I know countries where the high-minded Wollaston might have been obliged to fawn and bow in the anteroom of some lawyer in office, where his discoveries would have been submitted to the examination and criticism of some official underling; of having his writings and experiments appreciated by those who neither can conduct an experiment, nor weigh the force of an argument; and, after submitting to all these indignities—after having felt the full weight of the insolence of office—he might have had the humiliation to see preferred to his just claims, the unceasing importunity and the shameless effrontery of the impudent quack, and of the subservient sycophant. This, I will tell Mr. Babbage, is the real state of scientific men in those countries, whose manner of managing scientific concerns he affects

to rate so much above that of his own country, and *nisi exempla essent odiosa*, we might bring convincing proofs of the truth of our assertion from the scientific history of almost every country in Europe."

Our limits will not allow us to lay before our readers the masterly exposure of the fallacy maintained by Mr. Babbage and his backers, that either the interests of science or society at large are likely to be promoted, by calling upon abstract philosophers to discharge the duties of officers of state. The following calculations, however, of the comparative pecuniary exertions of France and England in behalf of science, incidentally introduced, are too striking to be passed over:—

"A very material difference between the Royal Society and the Institute consists in this, that the fellows of the former pay for their admission, whilst the members of the latter enjoy a pension. Now, there are at present 685 fellows of the Royal Society who used to pay about 4l. a-year for the honour of their fellowship, making in all an aggregate sum of 2740l. or 68,5000 francs. The members of the French Institute receive, or received formerly, each 1500 francs, making 10,250 francs of the public money. Now, we will ask Mr. Babbage, in which country the honour of belonging to the first scientific society is held in greater estimation—in that in which the fellows pay the honour with 68,000 francs, or there where they receive 10,250 francs, and the honour as an addition into the bargain?"

"But although France has a population of thirty-two millions, and England of twenty-two, and notwithstanding the high, flourishing state of science in the former country, we would undertake to insure the utter impossibility of finding seven hundred persons in France willing and capable of contributing for the benefit of science, and for the honour of belonging to a scientific body, an annual sum of 3000l.

"Mr. Babbage favours us with a table of the costs of fellowship of different learned societies; it would have been very curious if he had stated the annual sum thus contributed both by

the English and French nation towards the encouragement and benefit of science, and from the result a fair estimate might be drawn, in which of the two countries science is held in the greatest honour. We are not at all afraid that, in this case, the odds would be in favour of England. To imagine that there are six hundred Frenchmen amongst thirty-two millions willing and capable to pay 50l. or 1250 francs, in order to become members of a learned society, appears to us an idea so very ludicrous, that we cannot help smiling at the very thought."

In another number we shall resume this subject, and direct our attention more particularly to the concerns of *medical science*.

DISTINCTIONS CONFERRED ON MEN OF SCIENCE.

THE honour of being made Knights Commanders of the Guelphic Order, has been conferred on the following scientific men:—Messrs. C. Bell, Herschel, Babbage, Brewster, Ivory, and Leslie. The same honour was lately conferred on Dr. Chermiside, of Paris, long attached to the British Embassy in France.

PROGRESS OF THE CHOLERA.

JUST as we were going to press, we received the following intelligence on the engrossing subject of cholera. Accounts from Vienna reached London on the 4th instant, bringing our information down to the 17th ultimo. It appears that cholera is ascertained to have existed in that city so early as August 31st, but only in solitary instances, and apparently unconnected with contagion. On the 14th, ten persons died out of forty-one who were attacked; while on the 15th, of one hundred and thirty-nine attacked, sixty-four died. On the 16th there were one hundred and twenty-seven new cases, and fifty-eight deaths,

and one hundred and seventy remaining ill. These returns, however, only include the hospital patients, and we lament to say that many others, and those, too, among the higher classes, and whose names are well known at Vienna, have already fallen victims to the disease.—None of the remedies tried have been of any use—some have been decidedly pernicious, especially bleeding.

The death of one of the physicians, who had been indefatigable in his exertions, is mentioned by our informant with particular regret; and, in fact, an official account of the circumstances connected with it has been published. He was attacked with slight sickness on the 6th; on the 7th, unequivocal symptoms of the disease manifested themselves, and he died the same evening. A gentleman residing in the same house, and who had been out shooting all day, ignorant of his friend's illness, was attacked with diarrhœa within an hour after his return home; on the 10th the characteristic symptoms of the malady appeared, and he died on the 11th. A boy, son of the preceding, was seized at three o'clock in the morning of the 12th, and was dead at three in the afternoon. On the 13th, a child, 22 months old, was taken ill, and died the same day; and, on the 14th, a maid-servant, 18 years of age, was also seized with cholera, but was likely to recover.

By letters from Memel to the 20th of September, it appears, that between the 16th and 19th only two new cases had occurred, and one death. The proportion altogether has been 49 cases, and 26 deaths, in every thousand of the inhabitants—that is, of the cases reported; but it is known that here, as elsewhere, many persons had the disease without notice being given to the public authorities.

AN INTRODUCTORY EXTRAORDINARY!

To the Editor of the London Medical Gazette.

Tavistock, Covent Garden,
Oct. 3, 1831.

SIR,

I AM a country practitioner, settled for some few years in the neighbourhood of —, in Yorkshire; but I am not so settled as to have lost all my old town associations. I have still my yearnings after the resources of the metropolis; and particularly about this period every year I make it a point to be in London. A good introductory lecture is my chief delight; and that alone, if I can find one announced from some man of eminence, or to be delivered upon some important occasion, is always a sufficient inducement to bring me up to town. My old preceptor, "glorious John," is no more; and Sir Astley has retired from the business of lecturing, much to my disappointment. Yet, since I last heard either of these, I have listened to Charles Bell and to Mr. Lawrence with satisfaction undiminished. The occasion upon which I heard Mr. Bell was one of peculiar interest; it was at the opening of the London University in 1828; and I think I shall never lose the favourable impression left upon my mind of the bright prospects of that institution by the eloquence of the learned professor. My feelings were enlisted in what I was taught to conceive the "good cause" of supporting the University; and not even all the unseemly proceedings which have since occurred in that establishment—not all the changes and chances that have come upon its career, the dismissals, resignations, the breaches of discipline, and the disgraceful deficiencies of the governing body—can entirely wean me from the interest which I take in it, and which I can only refer to the imposing effect of the said introductory lecture. I have ever since been attentive to the progress (if I may call it so) of the London University, and have taken every opportunity of making myself acquainted with its arrangements; but I have never been able to attend on any of the annual opening days since the one just mentioned, until this very day, when, attracted not by the name of the individual who was to deliver the address (though I probably did expect

something from a person so permitted to take precedence), but by the peculiar circumstances under which I knew the establishment was about to open for the session, I took care that nothing should prevent me from being present. And such a scene as I have witnessed! Pained as I am by the general impression which it has left upon me, I would not have missed the absurd pleasantry of it for a great deal; nor would I wish the readers of the Medical Gazette, who were not present, to be deprived of all knowledge of this singular exhibition. Sir, I keep a regular journal or log-book, of such curious occurrences as befall me from time to time; and here are what I consider to be materials for a leaf or two. If the communication of them be acceptable to you, you are, I can assure you, most welcome to them, and I shall be at the same time much gratified by seeing them in print; so here they are in their original rough state, just as they were written upon my return to my lodgings:—

Oct. 3, 1831, *London University*.—The Professor of Midwifery of this place has just delivered himself of an opening lecture; and a troublesome job the poor man has had of it. In coming into the world the babe was little better than still-born; it was a poor, starved, sickly creature—any thing but creditable to the doctor and patient.—The gossips were astonished at the throes and efforts which were made in the delivery, and the constant recourse which was had to cordials by the accoucheur ever and anon. But allegory apart, I have heard one of the flattest, and, under the circumstances, one of the most stale and unprofitable introductory lectures from Dr. Davis this day, that I ever remember to have been an ear and eye-witness to. What a silly thing of his brother professors to allow *him* to open! The school of medicine in this establishment is understood to be remodelled and re-cast; great things are evidently expected from it, and I was glad to see so large an assemblage gathered in the theatre, to hear what the medical faculty had to say in its own behalf. Dr. Davis I had never heard lecture; but I expected much from the man who was permitted to stand in the breach in the time of doubt and difficulty. At length, in the “dab-chick waddled” (I could not help recollecting Pope’s line), and after a

few preliminary adjustments of putting on his spectacles, drawing forth his MS. &c. opened his mouth and began. He had an ample field before him, wherein to discuss the objects and advantages of a University established in a great metropolis; but it seemed more his wish to account for the absence of *religious* forms of education in this place, and to shew how the London University was open to all sects and denominations alike—“to Jew and Gentile, to Christian, Mahometan, and Hindoo.” He was pleased to be severe upon the old English universities, and alluded in terms, which he no doubt conceived to be pointed and pregnant, to the dangers of subscription; and clenched his argument upon the horrible consequences of perjury, with a long rignarole Latin quotation about the nature of an oath. The poor man was by this time in a pitiable state of exhaustion, and required recruiting. *He swallowed a glass of wine*. I have often before seen public lecturers have recourse to a glass of water for refreshment sake on the occasion of some great delivery, but this was the first time I ever saw the water-bottle literally set aside, and a decanter of wine, with a glass, introduced in presence of a large audience. But the midwife is the best judge; glass after glass was regularly thrown off after each heavy paragraph was delivered, and the audience seemed to feel for the jolly Professor’s necessities by looking round at each other, on the quaffing of every bumper, and venting their sympathies in a half-suppressed titter. I was particularly amused at one time, by observing his eye wander for a moment, in the midst of a long passage, from the paper to the wine—the lecturer’s lips smacked audibly—and the hand instinctively moved to the bottle, which it actually half-inverted! It is needless to say, if the Professor was given to perspiration before he touched the wine, in what a state he was when finishing the lecture. But to proceed:—Things went on flatly—very flatly—after all. No symptom of applause was elicited for the first half-hour—no well-turned phrase, or judicious sentiment, invited the approbation of the audience; and probably so it would have gone on to the end of the chapter, had not Professor Pattison’s dismissal been alluded to as “a change that would prove bene-

ficial." This drew from some score of juvenile auditors, who seemed waiting for the signal, a distinct peal of hand clapping; but there was nothing of the same sort demonstrated for the remainder of the lecture. And, by the way, speaking of Mr. Pattison, how strangely did the lecturer acquit himself! He positively spoke of the ex-professor as a distinguished anatomist, and one endeared to him by habits of intimate private friendship—yet he threw his intimate friend—his distinguished and able friend, overboard, in acquiescence with the publicly-condemned decision of the Council! The proceedings of the Council and the Professors he illustrated by the novel and original image of the going of "a piece of *mechanical machinery*." "Some," said the lecturer, "are of opinion that we cannot go on." (Here he took a glass of wine.) "Cannot we indeed?—Wait a few days!" It would be impossible to describe on paper the *sotto voce* point with which the doctor uttered these last two phrases; they were so irresistibly comic. But when he came to speak of the new arrangements, and the actual state of the school, much of course was expected: any person, however unskilled in lecturing, could have made here a hit for himself, and done some credit to his brethren of the faculty: but poor Dr. Davis did his best, and that best was—nothing. Hear his eloquent panegyric on Dr. Elliotson. After mentioning that this gentleman had been newly elected to the chair of Practical Medicine, the lecturer added, with inimitable grace, "He is *rather a young man*,—but he is an old lecturer and an old physician!" Little said is soon mended. Of Dr. Turner he only ventured to say, "He is very assiduous to his pupils."!! But Professor Lindley is immortalized by the niche he got along with the Lecturer himself in this eloquent prelection:—"Mr. Lindley is the Professor of Botany. I don't well know what to say about *him* (a laugh.) Whatever remnants of botany I ever had, I have lost them all; indeed, *I never had more than was sufficient to save me from rejection when I went in for my diploma!*" Good God! what a confession to proceed from the occupant of a medical chair! and a chair, too, in the University of London! What an encouraging example to be set before the pupils in a medical school!

Nor was the man in the slightest degree ashamed to make this confession before a public audience:—I wonder how he will like to see it in print.

Enough of this most unpleasant affair. I am grieved from my soul for the paltry predicament in which the University is placed by such an exhibition as this—not a soul who was present, I am bold to say, will forget it as long as he lives. I felt for the professors, who were face to face with the ungracious opening-lecturer, and hung their heads abashed at his foolish display. Often have I heard of "damning with faint praise," but never did I see the operation of sinking with laborious imbecility performed before. How unfortunate (though I should hope it may be otherwise) for the business of the establishment, with all its new arrangements, to have received its first impulse from such a hand? The opening lecturer, indeed, said something about this duty having been allotted to him in the order of the *rota*. When I recollected the auspicious first movement of that *rota*—a movement to which I have already alluded—and compared it with what I now saw, I could not help quoting the interrogatory of the poet:—

—————"Amphora cæpit
Institui: *currente rotâ cur urceus** exit?"

Sir, you now have the leaf from my log-book, which I promised to give you. Make what use of it you please, and believe me ever

Most obediently yours,
RUSTICUS.

LECTURES
ON
THE THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

— — —
Introductory Lecture—Oct. 5, 1831.

In appearing for the first time as Professor of the Principles and Practice of Medicine

* *Urceus*—vas angustum et ventricosum, cadi fere formâ.—VER. SCHOL.

in this University, it is impossible for me to enter at once upon the subject which I am destined to teach.

The novelty of seeing myself in another institution than that in which I have hitherto lectured, and in which it is still my happiness to attempt rendering myself useful to the rising generation of my profession by practical example and illustration, while I increase my own knowledge and endeavour to add to the general stock—the novelty of teaching in the first and only medical school founded in England upon the full and extensive plan of the celebrated and systematic schools of the continent and of Scotland—the novelty of teaching in a medical school constituting a department of an University, and that University established in the great city of the empire, in the greatest city of Europe, fresh and young, and therefore inexperienced, and sometimes possibly injudicious, but unencumbered by monkish habits and antique fashions, bent not down to support any one tribe or party, or sect, however dominant, nor proud and unkind enough to turn its back on any, but standing erect in all the beauty of a young and noble form, destined to a full growth and mighty strength, and a development of endless powers and excellencies; smiling and holding out its hand to all, of whatsoever sect or party, or tribe, or language, or nation; and intending to bestow upon the meritorious of all sects, sorts, and conditions, and upon the meritorious only, not upon those who have the accidental distinction of birth as well as upon the meritorious, those honours which it must one day have the privilege of bestowing; willing itself to learn, anxious to repeat no errors, and having the improvement and welfare only of mankind at heart;—all these circumstances produce feelings and reflections to which I must give utterance.

That I should have discontinued to lecture on the Practice of Medicine in St. Thomas's Hospital, may be a matter of surprise, and even appear to require explanation, to those who know the struggle which I made successively with a series of my predecessors, to obtain permission for the physicians to lecture within its walls, as the surgeons, and even the surgeons of an adjoining hospital in co-partnership with them, actually did; who know the dark persecution which, on account of my efforts, I underwent—the secret insinuations of incompetency and bad spirit—the attempt to remove me from the hospital after some years of gratuitous service, unless I would sign a promise that, although forbidden, like all the physicians, to lecture within the walls, I would not lecture even anywhere without; who also know, that, after all this, the extorted promise was torn to pieces, through the virtuous feelings of a general meeting of the Governors, and a

message sent me officially that I was free to lecture wherever I thought proper; that a regular medical school was next established, in which, up to the present moment, I took a principal part—which still flourishes, and long, I trust, will flourish—and that the medical officers are now allowed to attach themselves to any other schools they desire, the principle being acted upon by the liberal committee and governors, that the physicians and surgeons are elected to the charity, for which only the funds were given, and not to the school; and who know, moreover, that I not only had the satisfaction, at length, of seeing these results, but am on the happiest terms with all the officers, and all my colleagues, who are men of peaceful minds and high gentleman-like feelings, and that those whose ears were formerly poisoned are now my most cordial friends.

I determined upon the resignation of the lectureship of the Practice of Medicine before any idea was entertained that this chair would be vacant in the University; and even in the summer of 1830 I actually resigned, and consented to lecture last winter only at the solicitation of my principal colleagues. The great distance of the hospital from my residence had now become so serious an inconvenience, on account of the increase of my private practice, that I found it impossible to go more frequently to the institution than to make my clinical visits. I was merely a joint lecturer, and I fancied that, while I remained thus yoked, great success was impossible. But one single circumstance made my resignation a duty. I discovered that my colleague, with whom I am on the very best terms, and who is a most amiable man, in the complete course, which, according to our arrangement, he delivered during the season, and I in mine, upon the same subject, inculcated both principles and practice diametrically opposite upon almost every subject; that, to use his own expression, “we must have differed *toto cælo* both as physiologists, pathologists, and therapeutists, in many most essential points of doctrine and practice.”

To arrest teaching so unprofitable, so perplexing, so disgusting to the student—to arrest so ridiculous an exhibition, required no consideration. It was necessary for one to withdraw, and, as the junior, I felt it my duty to be the one.

Thus disengaged, I heard that this chair was vacant, and I instantly desired to occupy a post so honourable—a post affording so ample an opportunity of disseminating a knowledge of my profession. The plan of all the other medical schools of the metropolis has always appeared to me far too limited, and the instruction imparted to be of necessity superficial. Through the want of an university in London, medicine and surgery were long scarcely taught at all, notwith-

standing the great means presented by the population and the hospitals. The student was compelled to travel to France, Holland, or Italy, or, in later times, to Germany or Scotland, for the purpose of acquiring a true professional education; our own two Universities neglecting almost entirely to teach medicine, whether from the want of anatomical and clinical means, the hopelessness of rivalling the great continental and Scottish schools, or the idea that their proper end was to teach general knowledge, to impart only what all educated persons should know, or from the circumstances mentioned in a powerful and remarkable article in the last number of the *Edinburgh Review*, upon the Universities of England,—The ascendancy of the Colleges over the University—the subversion of the professional system by the tutorial—since (says the reviewer) time was when the Colleges did not exist, and the University was there; and were the Colleges again abolished, the University would remain entire; and when the University was paramount, the cycle of instruction was distributed among a body of teachers, all professedly chosen from merit, and each concentrating all his ability on a single object, and the whole youth of the University of equal standing, daily collected into large classes under the same professor;—whereas the colleges and halls are now elevated into so many little universities, into which houses the students are distributed, with little regard to ability or standing, among some fifty tutors, who are chosen from the fellows, notwithstanding that the fellowships were not founded for the purposes of teaching, and the fellow rarely owes his eligibility to merit alone, but to some fortuitous circumstances also, in the majority of cases.

The opportunities of teaching anatomy, surgery, and medicine, however, in London, became at length too great to be always thrown away; and the surgeons of the hospitals began to deliver lectures on anatomy and surgery, and afterwards the physicians upon medicine. These lectures were of limited extent, nor were systems of courses, for a time, delivered so as to constitute regular schools. The time, the trouble, and the expense of travelling to an University of medical reputation, rendered the emolument fairly to be expected on establishment in practice too high for the mass of the people to afford; and as the population increased, and more practitioners were demanded, home medical instruction was sought after by greater numbers every year—and this the more, as any one could practise without the license or authority of any University.

The lectures improved, and at length regular schools were established; yet, as they were all private, and could confer no privileges or honours, and those who re-

quired degrees went consequently to the old celebrated schools, while those whose only resource was the private schools had too small pecuniary means to devote much above a year to public study, these metropolitan schools remained scanty and superficial. The whole of anatomy and physiology, and morbid anatomy together, were disposed of in a course of little more than three months; the practice of medicine, and the science of chemistry, each in the same period, with only a lecture of one hour's duration three times a week; much of general pathology and forensic medicine was altogether omitted; and the whole of medical police, and the literature of the profession, were passed over; and things remain still in the same state, except that courses on forensic medicine are now about to be delivered.

It was left for this University to be bold enough to establish courses of six months' duration, in which full scope would be afforded the professors of laying before the student the whole body of medical science, to add the charms of varied illustration, to inculcate important points earnestly and repeatedly, and to introduce the student to an acquaintance with medical literature. These opportunities I not only did not enjoy in my former school, but could never hope to obtain; and I gladly attached myself to this new school of medicine (loud applause).

The mode of instruction by lecture, though by no means sufficient of itself, is in my mind of high importance. When a whole subject can be taught in a solitary course of lectures, and the exhibition of nothing is required, so that a mere delivery of statement constitutes the whole task of the professor, there can be no doubt that a good work, containing all the same information, might be studied in private with equal benefit; and, indeed, with this advantage, that it would probably, after costing less, remain in the possession of the student, to be consulted by him whenever he thinks fit. But when a circle of instruction is required,—when the subjects are numerous, and demand many courses of lectures and many professors, the student cannot be committed to himself. Without lectures he would become almost to a certainty bewildered, study at irregular intervals, and wander from one subject to another, getting little fruit from any; whereas the attendance on various lectures, at stated hours, creates an excitement and interest, as well as a regularity of habit, which are of incalculable utility.

In our science and art, however, lectures are, on another account, of superior advantage—are indeed indispensable. One part of the office of every medical lecturer is to describe objects of sense. The attempt to learn anatomy, physiology, chemistry, materia medica, or botany, would be ridiculous, without the inspection of the material

objects, and the principal phenomena. Of the practice of medicine and the practice of surgery, the same is true. Neither the professor of the practice of physic, nor the professor of surgery, can give his pupils a full idea of the phenomena of diseases, or of the administration of remedial means, without patients exhibiting the various phenomena of disease, and subjected to the exercise of our art. As cases, however, cannot be had at pleasure, so as regularly to illustrate a systematic course of lectures, it is indispensable to deliver the general description and history of diseases and their treatment in a distinct course, and to afford the illustrations from life in a totally separate manner, as they incidentally present themselves in a collection of patients: it is indispensable that there should be both a general course and clinical instruction. Yet, in the general course, material illustration is both possible and necessary. Representations of the various morbid changes by copious and well-executed drawings, engravings, and models, and actual specimens of these, and all the material products of disease, it is the duty of a teacher to present and explain; although, when I was a student in Edinburgh, the professor of physic never exhibited a single drawing, nor a morbid specimen. In these respects the University affords me great advantages. The museum is excellent, and with the assistance of the profession, may become unrivalled. And here I entreat the profession to contribute to it,—to preserve what morbid specimens they can, and deposit with us; remembering that we have no hospital to supply us, and must depend entirely upon individual contribution; remembering, likewise, that our museum is of indescribably greater utility than any others unconnected with a school;—that, while those are open only to the inspection of the profession, not merely is this open to the profession, but every preparation in it is laid distinctly before the students, and employed by the professors as a means of instruction: I therefore entreat the practitioners of this vast metropolis to render it, as they readily can, and at no expense, one of the first pathological museums in Europe. The drawings possessed by the University are, I believe, unrivalled,—at least I have no where else seen such a collection. Their accuracy and beauty, their scale, and their numbers, are the admiration of all who have seen them, and reflect such credit upon Dr. Carswell that he requires no panegyric of mine; and when the short period in which they were executed is considered, his industry becomes equally a subject of admiration with his talents. In the other great mode of instruction in the practice of medicine and surgery the University fails; and our school can never deserve the name of a great medical school while the defect exists:—a

hospital is imperiously necessary. It is true that we have a dispensary; but a dispensary must always be a miserable substitute to the student for a hospital. No medical university would grant the degree of doctor in medicine upon any who had frequented merely a dispensary. At a dispensary the majority of patients are so little indisposed, as to be able to go about. When seen, they necessarily pass in rapid review before the practitioner, giving him an opportunity of showing how practice may be dispatched, rather than how disease should be investigated: for, if the time demanded for the scientific and patient investigation of each case, and for demonstration and explanation to the pupil, were given, the poor creatures would be compelled to lose far more time than their condition in life or their strength would allow in attending at the charity. There is, besides, no certainty among the patients of a dispensary that medicine is regularly taken; no possibility of fixing their diet; no certainty of their continuing to attend, so that each case may be regularly followed up to its conclusion; no possibility of making daily observations. When cases are severe, and the patients confined at home, there is not only the same uncertainty of strict attention to the injunctions respecting medicines and diet, but the student must lose a great deal of time in running from one house to another; and the physician or surgeon will not visit all such patients daily with his pupils; and, indeed, his pupils cannot accompany him in these visits with any degree of regularity. In an hospital the patients are compelled to obey every injunction; being under the same roof they may be seen at pleasure any hour of the day, without loss of time, so that long and repeated observation of their cases is easy. When death occurs to a dispensary patient, and an examination is permitted, the student loses still more time; for he not only must go to the house of the family, but prepare the body, and afterwards restate it; and, in all probability, will seldom be accompanied by the physician or surgeon. At hospitals the examination takes place without any loss of time; the student has no where to go; servants prepare, and sew up, and wash the body; and the physician or surgeon usually superintends the inspection. So superior are the advantages of hospitals, that, as I have already remarked, certificates of attendance upon them are required at all medical Universities previously to examination for the doctorate; and although certificates of attendance at dispensaries are admitted by the Apothecaries' Company of London, and may be obtained at a cheaper rate than those of hospitals, the majority of English medical students voluntarily enter themselves to the medical practice of hospitals. The inferiority of dispensaries is, indeed, acknowledged

by their medical officers in the greater cheapness of their terms; and the Apothecaries' Company declare it in their demand of a longer attendance at them than at hospitals. It is, therefore, much to be lamented that the Apothecaries' Company admits dispensary attendance at all; for if, of the short period enjoyed by the medical pupil for the public study of his profession, a certain portion is necessarily devoted to witnessing cases, that portion should evidently be spent in witnessing them in what is acknowledged to be the most efficient manner, and if eighteen months can be spared for witnessing dispensary practice, they can be spared for witnessing hospital practice. Those who cannot see the necessity of hospital attendance, for the purpose of witnessing, without any loss of time, the most important diseases, and their minute investigation, and accurate and unrestrained treatment by the physician, cannot but admit the necessity of hospital attendance for the purpose of witnessing the great accidents and operations of surgery. The College of Surgeons can receive no certificates of attendance upon the surgical practice of dispensaries. If, therefore, the student must attend a hospital for half his experience, it is indisputably best that he should acquire the other half within the same walls. In speaking these, my sincere convictions, I feel some delicacy, because I am a hospital physician. But those who know me will, I am sure, acquit me of any interested motive, and, in truth, the medical clinic of St. Thomas's is frequented to the utmost of our desire, and I am not likely to have it in my power very long to remain attached to that great Institution. I will not scruple to add, that I think the student pays too much for hospital attendance in London, that the entrance should not be to medical or surgical practice alone, but to the whole range of the hospital, and that the sum which is paid to witness the surgical practice only would be a sufficient remuneration for the surgeons and physicians together; and I should rejoice to see the most meritorious among the senior students rewarded with the appointments of dressers to the surgeons, as well as of clinical assistants to the physicians, gratuitously. The last argument I will urge in favour of hospitals is, that they are also dispensaries; that they have a dispensary department, in which patients to the same amount are attended as at mere dispensaries. Besides all the inmates of St. Thomas's, the greater part of ten thousand out-patients are attended; and, although none are visited at home, this might readily be done without any farther trouble or expense, by the senior and best-informed students, to whom such a trust would be an incalculable benefit.

It is thus certain that the pupils of this

university must frequent hospitals for the purposes of surgery, and that many will frequent them also—and I think all ought to frequent them—for the purposes of physic; that they must be indebted to other practitioners than the professors—to others who are unconnected with the University, and possibly are lecturers in other schools, for a most important part of their education; that this cannot be celebrated as a medical school—that it cannot be said to afford a perfect medical education, till it possesses a hospital. Without a hospital, the Professors, it must be added, who teach the practical part of the profession, not only are deprived of the means of properly instructing their pupils, but lose the great advantage of proving to them the truth of their statements and the propriety of their precepts. One great source of my pleasure in teaching at St. Thomas's Hospital was the opportunity of shewing the pupils that I practised what I inculcated—of rendering probable, or proving to them, that what I advanced was true, and of referring from time to time for illustrations of my descriptions to cases which they had witnessed with me in the institution.

For the greater part of these important objects a small hospital would be sufficient—a hundred medical and a hundred surgical beds. This number of well selected cases, assiduously studied, would answer all ordinary purposes as well as the 458 beds of St. Thomas's, one half of the cases in which are imperfectly, or altogether unknown, to the pupils; and a hospital of this extent might, I am inclined to believe, be conducted at less expense than is generally imagined. But although such a limited extent might be prudent, and even necessary at first, I trust that the students of this University will one day enjoy the benefits of a large hospital—that the plan of the charity will be such as to admit of the greatest extension. For an important advantage is inseparable from a large hospital; not that of affording a large number of examples of the same affections, but of giving a probability of the occurrence of the more rare, nay, indeed, of the rarest diseases, accidents, and operations, during the period every student frequents it. Besides the opportunity of becoming fully acquainted with all the ordinary cases of medicine and surgery, it is indispensable to a full and perfect education that instances of every disease and accident which he may afterwards have to treat, should be witnessed by the student. Not only does the most elaborate description of a disease, or mechanical derangement, fall short of conveying an adequate idea, but the conception gradually fades away, or, if retained, is frequently not recalled when what was described chances to occur after a lapse of time; and probably not till another person

names the nature of the affection, do we see that it is what we formerly heard of; or if we suspect its nature, we still have our doubts. On the other hand, if diseases or accidents have once been seen, *oculis subjecta fidelibus*, when they again present themselves, they are immediately recognized. A striking exemplification of these remarks came under my observation when a student. A poor man, labouring under true scurvy, applied to a surgeon on account of the horrid state of his mouth, his gums being swollen and spongy, and bleeding, his teeth loose, and his breath offensive. The surgeon, not having seen a case of scurvy, supposed the disease of the gums arose from a bad state of the teeth, and extracted several in succession. He was then sent to another, of high eminence and enormous practice, who pronounced it a case of fungus hamatodes of the gums, and admitted him into his hospital, intending to resign him to his fate. Being visited, however, by a practitioner who had witnessed scurvy at a naval hospital, the nature of his disease was at once recognized: some lemon-juice, and fresh meat, and vegetables, were prescribed, and he was well in a week or two. The surgeons, who were not aware of the nature of the complaint, were well-informed men, and the disease was one which all have heard of, and the leading symptoms of which are universally known. But though formerly very prevalent and fatal in London, it now is uncommon, and from the want of having witnessed it, these two gentlemen thus committed a serious error. It is of great importance to the student that he should have witnessed also all the rarer accidents, and the rarer surgical operations. For all this a large hospital is indispensable, and I trust that we shall one day see a hospital connected with this institution, containing lying-in wards, for the purpose of an obstetrical clinique, and wards for the reception of mental diseases. If we but make a beginning, I feel confident that the public will support us. For to say nothing of the advantages of an hospital to the University, one is absolutely wanted in this situation. The eastern extremity of the metropolis, and the southern side, have the two great Borough hospitals, St. Bartholomew's and the London. The western extremity has St. George's and the Westminster. But between the east and west, on the northern side, there is merely the small Middlesex Hospital, and in this immediate most populous neighbourhood none at all; so that not only it, but the adjoining county, has not the advantages of any other parts within or around the metropolis. Were our University not in existence, the benevolent, on having these circumstances pointed out, would come forward; and if once a fund were established, legacies would be left as to

other institutions, which have already more than they can advantageously spend; and when the benevolent see that by their support they would do more than further the ends of charity—that they would, at the same time, contribute to supplying their country with a succession of highly-informed practitioners, the double incentive, I am certain, would realize our most sanguine hopes.

While I rejoice in the establishment of an English school of medicine, in a city, and on a plan, which will render it, if well conducted, equal to any, and far superior to most others, in the civilized world, I rejoice also that this school is a department of an university. Nothing is more to be desired, than that those who go forth into the world to practise the healing art should be men of excellent education. In most countries of the continent this is the case. The great body of practitioners there receive a general education at an university, previously to commencing the study of their profession. They in truth receive what should be the education of a physician, and are physicians. In this country those who carry on the great mass of practice—those who, in addition to their original occupation of apothecary, have risen to the office, though not to the name, of physicians—are indebted chiefly to their own exertions for even their professional knowledge and skill. Not only have all the lectures, excepting perhaps those on anatomy and surgery, been too scanty and superficial, and the clinical instruction conducted too generally in a most careless manner, so that clinical lectures were actually unknown in London a few years ago, and an extremely small number of those whose chief business in life was to practise medicine ever thought of entering to the medical practice of an hospital, or of even a dispensary; and no such systematic method of practical instruction, whether medical or surgical, as is proper—no organization of the students with more or less charge of patients, is yet established; but no better education is given by parents to those children intended for medical practitioners, than to those whom they destine for trade; and at the time when the best part of general education should begin, the youth, with all his capabilities of literary and philosophical attainment, is hurried off to mix draughts and weigh powders the greater part of the day, for several years. The portion of time thus consumed, and the sum of money thus expended, would enable the youth of our profession to attain every acquirement of a high education. The young men who come to our schools to prepare themselves for general practitioners are, in the majority of instances, as gentleman-like in their sentiments and manners, as intelligent, as anxious to learn every thing that their instructors are disposed to teach them, as those who are sent to Oxford or Cam-

bridge—as young men of whatever station in society, and in the previous enjoyment of whatever advantages. I trust that ere long the five years' apprenticeship to learn the business of the dispenser, or, as that might be learned in as many months, I should rather say, the five years' apprenticeship to waste their time as shopmen, will be abolished; and instead of the present preposterous regulation, of five long years in the shop before a limb is dissected—before a lecture on anatomy, chemistry, or any other subject is heard, and two years only in systematic public study, in dissecting and attending so many lectures, and in gaining the experience afforded by the medical and surgical wards of hospitals, and in reading, which previously would have been fruitless, the youth will, through the medium of such establishments as the London University, acquire a good classical education, a knowledge of the three great continental languages—the French, the German, and the Italian—and no inconsiderable acquaintance with mathematics, physics, and mental philosophy. By a change of plan, and by practicable facilities, I am confident that all this may be accomplished with no great increase of expense, and the young practitioner be ready for the commencement of his active career at the age of two or three and twenty; and no one will deny, that a given expenditure of money and of time ought to be made to produce the greatest possible advantages. These facilities will all be amply furnished by this University; and I hope that the Apothecaries' Company will one day be better pleased that those young gentlemen who go before them should adduce testimonials of a respectable classical and mathematical education, a capability of reading the German, French, and Italian writers in the originals, and the possession of a share of physics and mental philosophy, than if these young gentlemen proved they had consumed five years, when the mind thirsts most ardently for knowledge, in drug-mixing, or such poor and desultory instruction as a private practitioner has time to bestow, and which must be as nothing, before they begin to learn anatomy, physiology, and chemistry, systematically and practically at a public school.

An eminent scientific professor at Utrecht, in a pamphlet, just published in English by Mr. Faraday, in answer to Mr. Babbage's complaint that science is on the decline among us, says, "There are countries in Europe where no young man could think of studying medicine, mathematics, or natural science, with the help of Latin only, and without being prepared, before entering the University, with a sufficient knowledge of German, English, and French. The ignorance of foreign science in England cannot be attributed to want of zeal, but to a defect

in English education—the ignorance of foreign languages, which it was perhaps the business of the London University to amend." I believe that all the philosophers of the continent hailed the foundation of the London University with delight, as an institution which would spread among the general youth of England a far more useful education, and far more liberal principles, than the two old Universities of England have considered it their business to furnish to their clerical and more aristocratical alumni, and in which every science would be fully taught.

If I am told that this improvement in education will make the general practitioner equal in knowledge to the physician, I reply, that this will rejoice me beyond measure. I have no desire that the importance of physicians should be maintained by the depression of the general practitioner. If the physician is to continue as superior to the general practitioner as he formerly was, he must advance in the same proportion—he must not presume to think of preventing the general practitioner from stepping towards him—he must also step forwards himself, to maintain his advantage. The physician, whose means have allowed him to spend more time than the general practitioner in his literary and scientific education, in the subsequent study of his profession, and has spent it industriously; and who, when in practice, and exempt from the toils of midwifery and the other distractions which beset the general practitioner, and having not the whole of the art, but one branch only to cultivate, employs these advantages as his sense of duty must dictate, will always acquire every reasonable advantage, and general practitioners will gladly avail themselves of his assistance, and will be proud of him as a supporter of the character of the profession. The mass of the middle classes of society has begun a great movement in the acquisition of knowledge, in the discovery of rights, in the correction of absurdities, and in virtue and liberality of sentiment. The higher orders see the impossibility of arresting this progress, and titles and decorations will no longer command even notice, unless supported by real excellence. Among the higher ranks there are some, who, so far from viewing this movement of other ranks with dread, step forward to promote it; and the share taken by some of exalted rank and office in the foundation of this University, demonstrates a liberality and generosity which will ever do honour to England, and is worthy of all imitation. So ought physicians to act towards the general practitioner;—to make every effort to improve his general education and his professional knowledge. In fact, all those who lecture or practise at public institutions, act, whether they will or not, contrary to the narrow views of interest; for

they are occupied in imparting knowledge to the rising generation of general practitioners—occupied in endeavouring to make them as learned as themselves.

In me such narrow views would be the height of baseness, and would be the height of ingratitude ; for I hesitate not to avow—I rejoice in this public opportunity of declaring it—that to the general practitioners of England, Scotland, and Ireland, I am indebted for my success in my profession. When I commenced my professional career, I determined upon seeking for success by working hard, and by conducting myself as well as the infirmity of human nature would allow. I determined, however long I might wait for success, never to fawn upon and run after my superiors, nor to stoop meanly to my inferiors : never to intrigue for an advantage, nor to employ trumpery artifices for making myself known to the public. For many years I toiled, and saw most of my contemporaries, nay, of my juniors, who worked less, but were wiser in their generation, pass by me. I published work after work—edition after edition—and paper after paper was honoured with a place in the Transactions of the first medical society in Europe. I was physician to a large metropolitan hospital, and had attended there, and gratuitously out of doors, above 20,000 patients. But in vain. In 1828 my profession was no more lucrative to me, was as short of my actual expenses, as it had been in 1818. At that time the *Lancet* was pleased now and then to publish a clinical lecture delivered by me at St. Thomas's, and my practice at once doubled. The following year it published the greater part as I delivered them, and my practice doubled again. Last season the *Lancet* published them all ; the *Medical Gazette* followed its example, and my practice has now doubled a third time. This astonished me, the more as my clinical lectures were generally delivered with little or no premeditation, while all that I published myself had cost me great labour, many a headache, and much midnight oil. It was through the general practitioners, in the large majority of instances, and through general practitioners, for the most part, with whom I had not the honour of any acquaintance, that the publication of those lectures accomplished my success. To the body of general practitioners, therefore, I owe a debt of gratitude ; they have called me forth spontaneously from no interested motive, and I cannot exert myself too much in the education of their successors.

Conscious though I am that my lectures will not be without defects, I still can promise diligence, and the omission of no anxious care. The pupils will never find me maintaining a professorial distance, but always bearing myself as their friend, and only

as a student of longer standing than themselves. I thus have always conducted myself towards the students of St. Thomas's, and never met with rudeness, or even with neglect ; but, on the contrary, have ever experienced the most affectionate respect. In the ancient statutes of Oxford it was enjoined, that " after lecture the professors should tarry for some time in the schools ; and, if any scholar or auditor may wish to argue against what may have been delivered from the chair, or may otherwise have any dubiety to resolve, they should listen to him kindly, and satisfy his difficulties and doubts." In the spirit of this good rule I shall always act, and, in season, and out of season, not only during lecture but after lecture, and in my own house, whenever it may be desired, the student will ever find me ready to impart any information, and give him any counsel in my power. (*Reiterated applause.*)

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

DIFFERENCE IN THE EMPLOYMENT OF BLEEDING IN ENGLAND AND FRANCE.

BLOODLETTING is a remedy very differently employed in England, from what it is on the Continent. In this country, if a strong person be attacked by acute inflammation of an important organ, a full bleeding, from fourteen to twenty ounces, generally succeeds in checking the progress of the disease, and in many cases the necessity of its repetition is obviated ; in those cases where the inflammation is not subdued, the bleeding is repeated, the quantity of blood abstracted being proportioned to the violence of the disease and strength of the patient ; this, together with the use of purgatives, antimonials, &c. procures the speedy recovery of the patient in an immense majority of cases.

On the Continent, when bloodletting is employed, the quantity of blood abstracted at the outset very rarely exceeds ten ounces : this, in a large proportion of cases, is not sufficient to arrest effectually the progress of the inflammation ; hence the more frequent necessity of further depletion, which is effected either by the abstraction of a smaller quantity of blood from the system, or more commonly by the repeated application of leeches ; the patient at the same time taking an acidulated beverage, or a decoction of simple herbs, with, perhaps, an occasional dose of cas-

tor oil; so that although the continental patient may lose as much or more blood in the aggregate than the English patient, it is less calculated to produce the desired effect; while the neglect of the means of producing increased secretion from the bowels necessitates the more frequent abstraction of blood, and the patient, in the favourable cases, has to support a tedious convalescence.

LARREY'S METHOD OF TREATING COMPOUND FRACTURES.

Barron Larrey treats compound fractures of the leg in the following manner, and, as he states, with very successful results; although, from its not being more generally adopted, it may be inferred that the practice is not so successful in the hands of others. A junk is made with a piece of strong linen, and of pieces of straw bound firmly together, as in the London hospitals; on this are placed transversely three broad pieces of bandage; the limb is then placed on the junk, the foot resting on the heel; the Baron then covers the wound with a piece of rag, with holes cut in it, (*linge perforé*,) to allow the escape of any matter, which is absorbed by a quantity of charpie placed over the rag. A compress, wetted with a lotion composed of the white of three eggs, oil camphorated spirit, and oil. *lotionis plumbi*, is then put over the whole; the transverse bandage, wetted with the lotion, is bound firmly round the limb, the straw splints are approximated and tied with tape, as in a common junk; the limb is then left to itself, and the apparatus never removed or opened, on any account, till the expiration of sixty days, when the cure will be found to be effected.

ABSCESS OF THE LUNG, POINTING ABOVE THE CLAVICLE.

A lad, aged 18 years, was lately admitted at the Hospital of St. Louis, who had frequently been affected with cough during the winter. About eighteen months previous to his admission, he had become affected with pain of the back and under the left-shoulder blade. Five or six months after this, a tumor appeared on the left side of the neck, for which he went to the Hotel Dieu: this was in September 1830, when M. Breschet punctured the swelling and evacuated some pus. On his admission

at St. Louis, a fistulous opening was discovered above the clavicle. When the patient coughed, purulent matter was ejected by the aperture. The discharge, after a short time, became fetid, and the strength of the current of air through the opening was sufficient to extinguish a candle. He died June 6th. On post-mortem examination, a very large cavity was found partially filled with pus and communicating with the bronchiæ, as well as with the external surface. Several ribs were carious.—*Revue Médicale*.

LEUCORRŒA TREATED WITH SCALE CORNUTUM.

Dr. Bazzoni has recently detailed some cases in which he used the ergot with apparent advantage. About a scruple of the medicine was infused in eight ounces of water, of which one-half was taken the first, and the other half next day, in divided doses. Sometimes this sufficed to cure the disease, but if not, it was repeated.—*Annali Universali*.

REPORTS OF CASES OCCURRING AT PUBLIC INSTITUTIONS.

LONDON HOSPITAL.

Vesico-Vaginal Fistula cured by Operation.

ISABELLA PIGOT, ætät 28, a healthy married woman, admitted December 2, 1830, with a fistulous communication between the bladder and vagina. She stated that four months since, after a protracted labour of eighty-four hours, during which the bladder had not been relieved, she was delivered of a still-born child at the full period. Her recovery was speedy; but from the time of her confinement she had been unable to retain her urine, the constant discharge of which occasioned excoriation and great distress. On examination per vaginam, an opening sufficiently large to admit the point of a forefinger was discovered communicating with the bladder, at its neck, and apparently also involving a small portion of the commencement of the urethra. The opening was of an oval form, with its long diameter lying transversely about $1\frac{1}{2}$ inch from the orifice of the meatus urinarius. Although the flow of urine was constant, the retentive power of the bladder was not wholly destroyed, for during the examination several ounces of urine which had accumulated in it, escaped. The edges of the aperture were callous only to a slight extent, and circumstances seemed

favourable to obtaining a closure by operation.

Dec. 29th.—She was brought into the operating theatre and placed on the table, and the hands were fastened to the feet as in lithotomy. Mr. Luke introduced a silver female catheter into the bladder, through the meatus urinarius. Weiss's two-pronged dilator for the female urethra was passed per vaginam, and opened to its full extent; this exposed the fistulous orifice. Tenacula were attempted to be passed through its sides, but were found to be too little curved. Two hooks were therefore used; their points were introduced about an eighth of an inch from the internal side of the opening, and brought out at the same distance on the external; the sides were next pared off by two elliptical incisions made transversely in the vagina. To make the internal it was necessary to use a scalpel, with one-half of the blade bent at a right angle with the other. The whole of the preceding parts of the operation were performed with the utmost facility. There was some difficulty experienced in passing the ligatures for closing the wound. At first small curved needles were used, held in a *porte-aiguille*, but without success. Mr. Luke then tried larger ones, less curved, and succeeded in passing one on each side of the urethra, at a little distance from the edge of the wound, which when tightened perfectly closed the orifice. The dilator was withdrawn, and an elastic catheter was fastened in the urethra. She was sent to bed, and ordered to lie on her face, and allow the urine to drain on a cloth.

January 1st.—From the time of the operation no water had passed by the wound until to-day, when it was found that the ligatures had ulcerated from one side, and the edges of the wound were so far separated as to allow the escape of the whole of the urine.

3d.—All the urine passes by the orifice, which is larger than before the operation. The ligatures were removed, but the catheter was allowed to remain.

6th.—The elastic catheter was found to be stopped, and was withdrawn. Another ligature was passed in the centre of the opening, including more of the surrounding substance than before, which closed it completely. The silver flat catheter was fastened in, and she was placed on her face.

11th.—No water has passed by the wound, which appears closed. The ligatures produced ulceration and were removed, but the wound still adhered. A clean catheter was introduced.

15th.—The catheter had become stopped and the wound re-opened, and it is now nearly of the original size.

March 19th.—She submitted to another operation. Mr. Luke pared the edges of the opening by carrying a single hook through its sides and excising them with a common scalpel; a single ligature was also sufficient to keep them in contact. She was again

directed to lie on her face, with a catheter fastened in the bladder, through which the urine drained.

26th.—The ligature had produced ulceration, and was therefore removed. The sides of the opening were adherent, and all the urine flowed by the catheter, which was allowed to remain in the bladder, and the patient was directed to retain the same position.

April 9th.—The catheter was removed, and the fistulous orifice was perfectly closed.

After the removal of the catheter, there continued a *stillicidium urinæ* from the urethra; as, however, the parts regained their tone, this subsided.

25.h.—She was discharged cured.

BANDAGES AND SURGICAL APPARATUS.

Our attention has been directed to a course of practical demonstrations on surgery, which, we think, is calculated to be of considerable use to pupils. Mr. Chapman proposes exhibiting the various bandages, apparatus for fractures, dislocations, &c. as well as various instruments, comprising the stomach-pump, and such-like contrivances, in addition to those employed in operative surgery. The proposed plan is to give the pupil an opportunity of applying the apparatus, &c. on the living body.

BOOKS RECEIVED FOR REVIEW.

A Brief Sketch of the Progress of Opinion upon the Subject of Contagion; with some Remarks on Quarantine. By William Mac-michael, M.D., F.R.S. Fellow of the Royal College of Physicians, &c. &c. &c.

Elements of Surgery. By Robert Liston, Fellow of the Royal Colleges of Surgeons in London and Edinburgh; Surgeon to the Royal Infirmary; Senior Surgeon to the Royal Dispensary for the City and County of Edinburgh; Lecturer on Surgery, &c. &c. Part Second.

A Singular Case of Extensive Thickening of the Abdominal Integuments; dedicated to John Abernethy, Esq. F.R.S. late President of the Royal College of Surgeons in London. By Patrick Darbey, Surgeon, Member of the Royal College of Surgeons in London; Licentiate in Pharmacy, *Materia Medica*, and Pharmaceutical Chemistry, of Dublin; and in Midwifery, of the Lying-in Hospital. Second Edition.

Aur. Cor. Celsus on Medicine, in Eight Books, Latin and English. Translated from L. Targa's Edition. To which are prefixed a Life of the Author, Tables of Weights and Measures, with Explanatory Notes, &c. Designed to facilitate the Progress of Medical Students. By Alex. Lee, A.M., Surgeon. In Two Volumes.

LECTURES

ON

THE THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

LECTURE II.—Oct. 6, 1831.

General Observations — Circumstances which produce Disease—Explanation of Terms—Acute and Chronic—Active and Passive—Definitions of Disease—Different senses of the word Cause in medical language.

It appears, gentlemen, to be a law of the universe, that every thing shall undergo incessant change. Whether the universe be eternal or not; whether we believe it has existed, according to the opinions of some ancient philosophers, from eternity, and is to exist to eternity; or whether we are so to understand Scripture, as that not only the arrangement of all things, but all things themselves, had a beginning, and must have an end; yet while the universe is in existence, it appears to be the law of the Creator that every thing in it shall undergo incessant change.

The material and the animate world are in the same predicament. The most minute aggregate of matter, and the largest material bodies, appear only destined for certain periods of continuation in their existing state. We see with respect to our own earth, that countries are continually lessened and destroyed by the encroachments of the sea and by eruptions; and on the other hand, from similar circumstances, other countries are produced; so that it is probable that the appearance of the earth at present is totally different from what it once was, and that after a period it will be totally different from what it now is. Even with respect to other worlds, there is every reason for astronomers to believe, that many have been destroyed, and that some worlds which

are now seen are but fragments of others which have been broken to pieces.

With respect to the animated part of the creation, every vegetable, every animal, has but a limited period destined for its existence. This period is exceedingly various; some animals are destined to live but a few hours, others again would appear to live for centuries.

But besides this definite period, every animated being is liable to be cut off long before its natural period has arrived. Animals and vegetables are all exposed to violence of every description, not only to mechanical violence, but to the destructive operation of ten thousand causes—ten thousand circumstances; and to disturbance from the cessation of the circumstances which are necessary to their existence. One animal is destined to devour another while in its prime; nay, to destroy the element of what would be the young—to destroy the eggs, for example, of another; and myriads of insects are continually destroyed in storms. Constantly, therefore, the limit which providence appears to have placed to every thing is curtailed—every animal and vegetable is subject to be cut short long before that limit is reached; so that there appears to be a perpetual struggle throughout nature—the Creator having, on the one hand, invested every animated being, whether vegetable or animal, with a power to exist for a certain time, and power to resist injurious agencies; and having provided, on the other hand, injurious agencies, without number, to injure and to cut them off before their time.

It has been said by some philosophers, that to look at man one would suppose that he was destined to live to all eternity; that, at first sight, such a machine as the human body, unless destroyed by external violence, would appear capable of lasting for ever, and it is by experience alone that we are taught the contrary. *Primo statim aspectu talis machina, nisi forte vi externa corrupta, in omne ævum durabilis videtur; et quidem solâ experientiâ contrarium docemur.*

However, there is nothing in the appearance of the human machine which would lead us to suppose that it could last for ever. Whatever we know of nature can only be learned from experience, and it would be as correct to say that because it is summer we should believe it will be summer for ever, or because it is day we should believe it will be day for ever, unless we have contrary experience, as it would be to say, that the human machine in itself appears capable of lasting for ever. We can learn nothing from taking a partial view of things—it is impossible to form a judgment of nature except by taking a continuous and enlarged view. It would also be contrary to all analogy to suppose that the human machine is capable of lasting to eternity.

With respect to the injurious circumstances which are positive, and to which animals are exposed, and by which they may be cut off before their full period has arrived, they are those in the first place of mechanical violence, and likewise those of a specific nature. Many animals and many vegetables contain within them materials which are destructive to the life of others.

They are liable to be destroyed, also, from a want of suitable external circumstances, for a series of action is incessantly going on in every animated machine, and those actions are maintained by external circumstances—by a certain degree of temperature, by a certain surrounding atmosphere, and also by a certain supply of matter to be taken into the mouth or stomach, or something equivalent. The deprivation of any of these may put a stop to existence, or may impair it; the excess, on the other hand, of some of these, will have the same effect. The excess of food may destroy or injure life, and the excess of heat may cause serious injury, or absolutely consume the body. Besides this, the depraved quality of those external matters which are necessary to the continuance of life, will have an injurious effect: the unwholesomeness of bad food is a circumstance particularly illustrative of this.

One of the most common causes—indeed, I may say, the most common cause, of diseases—is a deviation with respect to external temperature. A certain degree of heat is required for the support of life, and a deviation in that particular is the most common cause of the diseases that we see here. An excessive degree of heat produces one set of effects, an excessive degree of cold produces another, and an alternation of the two from the body being suddenly exposed first to the one and then to the other, more especially if this exposure be partial, is attended by the most serious effects. The greater number of diseases are inflammatory, and the most common cause of inflammation is sudden alternations, or other unfavourable circumstances, in regard to temperature.

Bad air is also a common cause of disease,

but this does not arise from the want of oxygen in particular, as has been imagined, but from the presence of certain substances of deleterious quality. I believe it is found that the quantity of oxygen in the air is the same in almost every country and every situation; and it is the presence of other things, in addition to the oxygen, which produces the injurious effect. We see the effect of the bad quality of the air in unhealthy situations, where persons are sallow and bloated, and carry about with them marks of disease visible enough to others who come from a healthy spot, although these are not allowed by the parties themselves to exist, simply for this reason, that they are so accustomed to what they witness that they conceive it to be their nature.

The ill effects of unwholesome food are seen every day. The body is rendered feeble; and when this takes place, whether from bad air or bad food, it becomes an easy prey to any other cause of disease which may present itself. Want of the rest necessary for the refreshment of the body has also the effect of producing disease. Excessive action, too, either of the mind or any part of the body, has likewise the same tendency.

Thus disease is continually produced from mechanical violence, from the presence of injurious agents, and from errors in regard to those agents which are absolutely necessary to the support of life, whether it be the error of excess, deprivation of their proper quantity, or deprivation of their qualities.

This, however, is not all. When a disease has been induced, it frequently happens that a tendency to that disease is transmitted to the offspring of the sufferer, so that it requires no exposure of such offspring to the particular cause of the disease in order to become its victim; but at a certain period of life, unless placed in very happy circumstances—and perhaps in spite of the happiest circumstances possible—the disease under which the parent laboured appears in the child, or in still later offspring, and possibly cannot be controlled. Again, independently of the external circumstances to which the offspring is exposed, and inherent disposition to disease, original malformation of certain parts of the body, at last so disorder its functions, that sooner or later disease appears which may end in death.

Now when disease takes place, the functions of the body go wrong. A series of actions is continually taking place in the body, and some of these, when what is called *disease* occurs, become deranged. The circulation of the blood is altered; more is accumulated in some parts than there should be, and less in others. The temperature of the body is altered; it is too hot either partially or generally, or it is too cold. The feelings of the body are altered; they become too acute or too dull, or they become otherwise

wrong. The strength of the body likewise is changed; in some few instances it is increased, but in the great majority it is impaired. What is done naturally in the body before this change takes place, is now either done too little or too much, or in a depraved manner. The products of the body are likewise altered; the sweat is not natural in its quality any more than in its degree: the urine becomes altered in its quality, and the secretions poured forth from the intestines likewise in theirs; and I have no doubt that the excretion from the bronchial tubes is likewise changed in its constituent proportion. At last even the structure of the body will become affected. Not merely are the actions of the body altered, and the products excreted from it, but the very substance of the body itself will become changed.

With respect, however, to all the changes I have just enumerated, they must evidently be in a certain intensity, a certain degree of them must exist, for us to say that disease is present. A change, although, strictly speaking, you might say it was a disease, may be so inconsiderable, that one would be laughed at for calling it a disease. A slight spot upon the surface, a single point not larger than a flea-bite, no one would think of calling a disease; and yet, if there were a large number of these, though the only difference consisted in amount, the nature and degree of each being exactly the same, we should not hesitate to say that disease was present. Therefore, when a deviation with respect to function or structure takes place, there must be a certain extent of it, or a certain intensity of it, one or the other, to justify us in saying it is really a disease. Logically and strictly speaking, disease is said to be "an aberration of function or structure of one or more organs from a sound state." You will find this mentioned in some books as the definition of a disease. But this is hardly sufficient; because, with respect to structure a part may be sound, and even with respect to function, and yet be in a state of disease. A part may grow to a much greater size than natural, there may be diseased bulk of the organ, although the structure is healthy. This is a rare occurrence, but sometimes it does take place. Generally, where there is increased bulk there is diseased structure; but it is possible for a part to be enormously large without being altered in structure, and yet the person may be said to be labouring under disease. A person with an enormous liver, or brain, though no unhealthy change could be discovered in its texture, would nevertheless be pronounced to be in a state of disease.

So with respect to the fluids; they also suffer very great changes, and yet there may be no fault of function. In the disease called *anæmia*, where the blood is deficient in quantity, the disease may really be quite independent of any fault of the body itself.

A mere want of nourishment may cause the blood to be of a diseased quality—that is to say, not to contain its natural elements, but to be very watery—to be thin and pale; the whole body becoming white or tallowy in appearance, and yet no function can be said to be diseased, at least excepting through this. The body is ready to do all that is required of it, if proper food be given. Therefore this definition of disease, you find, is more or less exceptionable. Besides, in a large number of diseases, the quality of the fluids is altered, and it is essential to a correct definition that this should be taken into account.

With respect to the extent of affection which is necessary to exist in order to constitute a disease, there must be a great difference in various individuals; for the health of different persons is exceedingly various. What is health to one man, would be disease to another; the degree of strength which is natural to a delicate person would be considered downright weakness in another. To obviate any difficulty of this kind, you will sometimes find added to the definition of disease which I have already given, "rendering assistance necessary." The definition given in Dr. Gregory's *Conspectus* is—a disease is present when the customary actions of the body are either altogether impeded or performed with difficulty and pain. "*Morbus adest, quum corpus tantum a statu sano deflexcrit, ut solitæ actiones vel prorsus impediuntur vel ægre aut cum dolore perficiuntur.*"

Disease, therefore, may generally perhaps be defined to be, "an aberration of function, or structure, or size, of one or more organs; or of the quality of the fluids, from the sound state, rendering assistance necessary."

This, however, you will observe, is only a definition of disease in general, and I shall have to make some remarks upon the definition of each particular disease hereafter. You will see thus that diseases are neither more nor less than alterations in the physiology or anatomy of the body—that they are morbid physiology and morbid anatomy. This morbid state of physiology and this morbid state of anatomy, are together called *pathology*. The doctrine of diseases, whether regarding function or composition, is called pathology. There is an inclination at the present day to limit the word pathology to morbid anatomy. That, however, I think, is quite unjustifiable; for pathology is the doctrine of disease, whether it relates to function or structure, or both. Pathology, therefore, is an unhealthy state, if I may so speak, of physiology and of anatomy; the composition of the fluids being comprehended under the term physiology as well as function—size being comprehended under the term anatomy as well as structure.

Now diseases are often divided into those which are functional and those which are

structural, but it is very common for the one to terminate in the other—for diseases which are at first purely functional to become at last structural; or at any rate many organic diseases do not at first exhibit themselves as such, but are ushered in by a change of function. It is possible that a minute change of structure may exist long before it is discovered, and that minute change is enough to explain the alteration of function; but many diseases exist long, to all appearance, as mere functional disturbance, before they become structural. Many diseases remain functional, at least they go through their course as a disturbance of function, never affecting the structure; but structural diseases almost always disturb function. It is evident that if the structure of an organ which is to perform a certain duty be much altered, that duty cannot be well discharged.

Structural diseases are sometimes called *organic*. I believe that the words structural and organic are used synonymously, to express those diseases which consist in a change of composition and arrangement of the organ itself, and not a mere alteration in the mode in which it does its duty. Perhaps the word organic is preferable to the word structural; and on this account, that some diseases of this description do not appear to consist in any alteration of structure, but merely in a diminution or in an excess of bulk. Now in those cases which, though they are rare, nevertheless do sometimes occur, in which an organ wastes, or becomes larger than natural, and yet appears otherwise healthy, the affection cannot exactly be called structural—the word organic better applies to them, and therefore, altogether, the term organic may be preferred to structural.

There has been an attempt by some to call the one set of complaints supposed to be merely functional—*disorders*; and the others which are structural or organic—*disease*. For instance, to call dyspepsia, or diabetes, a “disorder;” and ulceration or cancer of the stomach, or ulceration of the kidneys, “disease.” You will, however, not find this generally adopted. It might be very well if all persons agreed to adopt the terms in this sense. But that is not the case: indeed, so far from it, that, in most books, the expression organic or structural *disease* occurs, which would not be necessary if every one adopted the word disease to signify in itself a structural affection. Nay, so extensively is the word disease employed by some persons, that even accidents, as dislocations or fractures, are called disease. You will find, in Cullen’s Nosology, that dislocation and fracture are arranged under the class of local *diseases*. The word disease, then, is used by some nosologists very extensively; they employ it to signify accidents, mechanical affections, dislocations, hernia, and every thing of that description; and it is

used by almost all writers to signify both functional and structural affections. I shall not, therefore, attempt to use the word disease to signify organic affections exclusively, but all depraved conditions, whether functional or organic.

Disease may be considered accordingly as it is local or general. Some diseases affect only one part, and others are supposed to affect the whole system. Fever, for example, is supposed by many to be a general affection, and it has been instanced as such; others, however, now deny that there is any such thing as a general disease, and assert that fever is only an inflammation of one part or other of the body. You will find that Broussais maintains the latter doctrine. However, I can entertain no doubt that there are such things as general diseases; and it appears to me that scurvy is of this description, for every fluid of the body seems vitiated, at least the blood throughout the whole body is so, and all the solids appear to be in a similar state. There is no one part of the body that can be fixed upon as the seat of the malady, and therefore I think scurvy a fair illustration of general disease. So with respect to ague. I cannot discover any reason for ascribing the disease to any one part of the frame, and I therefore think that it also appears an instance of a general affection.

Diseases are also different from each other accordingly as they are acute or chronic. Some diseases come on suddenly, last usually but for a short time, terminate either in health or death, *cita mors venit aut victoria lata*, and are called *acute*. Other diseases last for a long time, perhaps come on slowly; but whether they come on slowly or suddenly, if they last for a long time they are called *chronic*. Acute diseases, however, will sometimes, instead of terminating in health or death, become chronic—that is, become less violent in their degree, and go on for a length of time. Diseases, therefore, are to be considered acute or chronic according to their duration.

You will find that diseases are also considered by some accordingly as they are active or passive—that is to say, accordingly as they are attended with a degree of violence or excitement of the system, or no excitement at all. You will find some persons, indeed a large number, use the terms active and passive, and acute and chronic, synonymously; but this is an error against which I am particularly anxious to guard you. It does not follow because a disease is acute—that is to say, exists for a short time, and then terminates—that it is necessarily attended by violent symptoms; nor does it follow, because it lasts for a length of time, that these symptoms should not be active. This is every day illustrated in the case of rheumatism; it is daily spoken of as acute or chronic, and active or passive; the term

acute being used indifferently with active, and chronic with passive, so that, in the chronic form of the affection, a person would not think at first of applying such remedies as in an acute attack, taking it for granted that, as the disease is chronic, there is no violence, but that a slowness of mischief is going on, and that the remedies for the active acute state are improper. But you see cases of rheumatism every day, which have lasted for six or twelve months, or even longer, attended with all the symptoms of an acute disease—that is, attended, if not by quickness of pulse, by heat of the parts, and if you take away blood you find it buffed; it would, therefore, be a serious error if you were to consider active and passive as synonymous terms with acute and chronic, because in acute diseases, the word acute refers simply to their short duration, and in chronic diseases, the word chronic simply to their long duration; whereas the word active refers to the violent disturbance going on in the system or part, and the word passive to slow changes, changes not of a violent description. A chronic disease may be active, and an acute affection may be passive. A person with an acute affection may lose all his powers, and the whole functions of the body may go on in the most languid way; and therefore acute and chronic are one kind of thing, active and passive are another. An acute affection cannot be chronic, but it may be passive; and a chronic affection cannot be acute, but it may be active.

You will find diseases differ also according to their uniformity of duration. Some diseases continue with uniform tenour during their whole course—without any very great deviation from the beginning till the end, and these are called *continued*. Other diseases, again, undergo a very great remission at regular periods, or at least pretty regular periods, and then they are called *remittent*, the symptoms not going off entirely till the disease ceases altogether, but undergoing such a relaxation of severity at such periods, as to acquire a character from this circumstance. Other diseases, again, will cease entirely from time to time, and generally too at stated times, and recur again at certain intervals as long as the person is affected with them; these are called *intermittent*. This is particularly seen in the case of fever. Fever may hold a pretty uniform course, never ceasing at all, or particularly diminishing, during the twenty-four hours, till its close, and we then call it “continued” fever; it may last for a day, a week, or several weeks. Others are characterized by a sudden diminution in the degree of heat, violence of pulse, of thirst, and all the other symptoms, at a certain period in the twenty-four hours, and perhaps at longer intervals, but not ceasing entirely: such is the character of “remittent” fever.

Others, again, cease entirely; the patient will be attacked at a certain hour; he ill a certain number of hours, and then be perfectly well, with the exception perhaps of languor: the fever then receives the name of “intermittent.”

Diseases differ, therefore, accordingly as they affect function or structure; accordingly as they are local or general; accordingly as they are acute or chronic; accordingly as they are active or passive; accordingly as they are continued, remittent, or intermittent.

Diseases likewise differ exceedingly in their true inherent nature, independently of any other circumstances. They differ also as to their causes. Some are produced merely by an aberration as to some of the circumstances which are necessary to the support of life, such as the excess of temperature or food, or a deprivation of food or air, or a diminution of either food or air. Others, again, are produced by specific causes, by the agency of particular substances, the nature of which cannot be comprehended; such, for example, is ague, which is produced only by a certain exhalation, and such is small-pox, and all those diseases which acknowledge a peculiar specific poison for their cause. Diseases differ likewise according to the organ which they affect. There are some diseases which can affect almost every organ in the body. Inflammation is one which affects every part of the frame which has vessels; but there are certain diseases that can only affect particular organs; diabetes, for example, can affect, so far as we can judge of it, only the kidney; and the tendency to produce gall stones can evidently affect no other part than the biliary system. Therefore diseases differ, in addition to all the circumstances previously mentioned, accordingly as they may affect any part of the body at large, or are necessarily confined in their operation to particular organs.

With respect to the *causes* of disease, you will find them generally divided by authors into two, the *remote* and the *proximate*. The remote causes, again, are divided by systematic writers into two more, *predisposing* and *exciting*. The word cause, however, is in these cases used in a totally different sense. When we speak of remote causes, a very different idea presents itself to you than when we speak of proximate causes; in fact, the cause of the disease, properly speaking, can only be remote. For example, the remote cause of fever may be bad food, and the depressing passions; and the exciting cause may be, according to some, a specific contagion. Now the remote causes of the first description are called *predisposing*; they render the body liable to become the prey of something which has a tendency to excite the disease. The exciting cause of the disease might have had no effect unless the body had been predisposed, and the predisposition

might not have had the effect unless the exciting cause had occurred. A circumstance, therefore, inclining the body to become the subject of disease is called a predisposing cause—*causa prædisponens*; that which actually excites the disease, exciting—*causa excitans*; and both together are called *causæ remotæ*. They are called remote, I presume, because they are a little distance from the disease itself, and because the proximate cause is, to all intents and purposes, close to and all but the actual disease, and, in one sense at least, it is the disease itself.

The application of this term gives rise to a great deal of confusion to the student. You would imagine that disease could be nothing more than disease; and to call the disease the proximate cause would be thought absurd; but the reason of this I will explain. In defining any particular disease we are obliged to take into our definition only what we observe, just as the naturalist defines any flower, or any mineralogical specimen, merely taking what is the object of sense, and describing it with all the marks together; and that is called the definition of a disease. For example, in jaundice you take the yellowness of the skin, the yellowness of the eyes, the yellowness of the nails, the whiteness of the faces, the high colour of the urine, together, and you say that the patient certainly has jaundice. The jaundice is not the disease, strictly speaking; but the collection of symptoms under which the patient labours is called jaundice. The word disease, by nosologists, is thus applied not to the single cause of all these symptoms, but to the collection of symptoms. Take epilepsy: a person falls down foaming at the mouth; struggling in every limb; perfectly unconscious; and afterwards, when he ceases to foam and struggle, he lies senseless; such a person is said to labour under epilepsy. These particular symptoms, blended together, occurring in succession, are called epilepsy. Now in Cullen's, and other methodical nosologies, you will find the disease defined according to mere symptoms; all opinion, all cause, is excluded; you take merely the symptoms, and you call them the disease, and it is perfectly right that it should be so. But these symptoms must have a cause—there must be a cause for this disturbance in epilepsy—there must be a cause for the bile going into the blood in jaundice, appearing in the urine, and not being able to find its way to the fæces. The cause of the epilepsy, or of the jaundice, is the circumstance that produces all these effects, and that is considered to be the "proximate" cause. If the epilepsy arose from a piece of bone depressed upon the brain, you would say the proximate cause of the epilepsy was the spiculum of bone. If the bile were obstructed because a calculus was impacted in the hepatic duct, you would say the impaction of the calculus was the proximate cause of the jaundice. You therefore

observe that the proximate cause is, in fact, the disease itself—the actual disease from which the symptoms arise. The remote causes are those that predispose to the disease, or actually excite it; the proximate cause is the circumstance to which the predisposing and exciting causes have given rise; and this circumstance, when present, produces all the external symptoms—the visible changes.

But the word disease, when you come to any specific affection, is, in a nosological sense, applied merely to a set of symptoms—to that which we can comprehend—which is discernible; and as nosologists, we should not apply the word disease to the cause of all these symptoms—but say it is the proximate cause. You will find, however, when speaking as pathologists, and not as nosologists, that persons inquire, what is the actual disease in this epilepsy? What is the actual disease in this jaundice? Is it an enlarged pancreas pressing upon the ducts? Is it a calculus sticking there? Is the disease a contraction of the sides of the ducts, or what is it? But that is a different sense of the word disease, and it is necessary that you should know that the term is employed by methodical nosologists, and must be so by me, to signify a collection of symptoms, and not the true cause which is at the bottom of those symptoms; for though we might be inclined to say that this was the real disease, yet it is not so considered, but has received the appellation—proximate cause.

I trust, therefore, from the explanation now given, you will hereafter escape any confusion which might otherwise arise, because for the want of understanding this, you will hear persons quibble about what is a disease and what is not. It is necessary to know that a set of symptoms, following in a certain order, or united in a certain collection, is called a disease; and the immediate cause of all these symptoms—which some say is the real disease—is called by the best writers the proximate cause.

DR. PROUT ON THE APPLICATION OF CHEMISTRY TO PHYSIOLOGY, PATHOLOGY, AND PRACTICE.

In Answer to certain Strictures of

DR. WILSON PHILIP.

To the Editor of the London Medical Gazette.

SIR,

HAD I not promised to reply to Dr. Philip's observations, I am not sure if I should have now done so, as after a second perusal of them, I find them still less to the purpose than they first appeared to me to be. Having made this promise, however, I cannot now well

retract, and accordingly I proceed, at the risk, I fear, of being considered a little tedious, to notice a few of the more prominent details.

1. Dr. Philip commences by alluding to a conversation which took place between himself and me, and which he calls "private." To obviate any misunderstanding on this point, I may say that the conversation alluded to took place in the apartments of the Royal Society, in the presence of two witnesses, who, I dare say, well remember the substance of what passed on the occasion.

2. On the subject of metaphysics, I shall only observe, that the sense in which this term was used, whether right or wrong, could hardly have been the cause of the Doctor's mistake, as he evidently saw this. My authority for this assertion is a note appended to the first page of his first observations:—"It is remarkable that Dr. Prout here uses the word psychology as synonymous with living action, while in the foregoing sentence he uses it as synonymous with metaphysics. *Is then the term living action synonymous with metaphysics?*" If these words do not convey the idea that he saw the matter in question, I am quite at a loss to understand them: the disapproval of the sense, is quite another question.

3. The next observations I think it necessary to notice are the following:—"Can Dr. Prout assert, that the laws of the living animal body are not as legitimate a subject of experiment as the composition of the fibres of which it consists? Are they less important, less conclusive, or placed more beyond our reach, than those of Lavoisier?" To this I reply, that I have no where asserted, nor dreamed of asserting, that these laws are not legitimate subjects of inquiry; and as for their importance, I have always considered this to be first rate. What I am disposed to assert is, that these laws are infinitely more difficult and beyond our reach, than those of chemistry, and, consequently, that experiments made to investigate them, are infinitely more likely to be erroneous*. Every body knows that

the metaphysical department of physiology (I use the word in the same sense

familiar illustration of the principal grounds upon which human knowledge rests, may not be deemed altogether superfluous:—

1. *Mathematical grounds.* Two and two must make four; we cannot conceive the contrary.

2. *Universal and perfect experience.* Sulphuric acid and potash, when mixed together in certain proportions, have in all ages formed a salt, called sulphate of potash, and from this universal experience we conclude that the same thing will always happen in future.

3. *Partial and imperfect experience.* When we apply a mechanical stimulus to a certain part of the brain of an animal, a distant set of muscles will be convulsed; say nine times in succession. When a person swallows a dose of calomel, he will be purged, perhaps as often. But the tenth time, from some reason unknown to us, the distant muscles will not be convulsed, or will be differently convulsed; and the person who swallows the calomel will not be purged but satiated; and this single failure is sufficient to throw an air of uncertainty, with respect to the future, over these points; that is to say, we are not absolutely certain, in any instance, what will take place in our next experiments. Hence, all knowledge founded upon partial and imperfect experience, is likewise imperfect, and amounts only to the *probable* (the probability being greater or less as the experience on the particular point, is more or less perfect), and this unfortunately is the case with by far the greater proportion of physiological and pathological knowledge.

The above applies to the experience of an individual himself; but the greatest part of our knowledge must be necessarily derived from others. Hence, it becomes necessary to inquire, how far the above grounds of our knowledge are liable to be influenced by the character of the observer himself; or, in other words, to inquire into the value of testimony:—

1. Mathematical knowledge is independent of the operator, and consequently not liable to be influenced by testimony. No one supposes that two and two ever made any thing else than four, whether the author of the addition was a knave or an honest man, an idiot or a philosopher.

2. In knowledge founded on universal experience, it is often necessary to take the character of the operator or witness into account, not, indeed, usually with respect to the essential fact, but with respect to many of its concomitant circumstances. Thus, an expert chemist on mixing sulphuric acid and potash in the proper proportions, will obtain the sulphate of potash in beautiful crystals; a clumsy or inexperienced chemist will obtain no crystals at all, or very imperfect ones; and these two operators on becoming narrators of their experiments, though agreeing about the fact of the formation of sulphate of potash, will give very different versions of the concomitant circumstances.

3. In knowledge founded on imperfect experience, the character of the witness, and consequently the value of his testimony, is of infinitely greater importance; for here he may not only be wrong as to minor points of little value, but essentially and radically wrong as to the principal fact. A clever and faithful operator will obtain certain results, and narrate them accordingly; but your clever operator may be a knave, and narrate what he does not obtain; or he may be a prejudiced man, and narrate only half the truth; or he may be a bungler, or a compound of the bungler and knave, &c. &c. all which may happen from the barely probable character, of the point in question, without our being able to prove the contrary; and if we have no means of forming a just estimate of the degree of credit to be attached to the witness, we must be content to remain in doubt on the point in question.

* Physiologists and pathologists are exceedingly apt to lose sight of the grounds upon which their department of knowledge is principally founded, and to argue and assert with all the confidence of mathematicians and chemists. For the sake of the younger members of our profession, who are most apt to fall into this error, the following

as before) has always been considered as the region of fancy and hypothesis, and as uncertain, even to a proverb. The reason of this lies in the very nature of the thing itself, which, for the most part, is beyond our comprehension. Were the laws of the living animal economy as capable of being understood, and of becoming the subject of demonstration, as the laws of mechanics, or even of chemistry, the study of them would be independent of these and all other auxiliary branches of knowledge; but as this, from the nature of things, never can be the case, I have always agreed with those who think it their duty to call in the assistance of any auxiliary means that promise to throw light upon the subject. Of these auxiliary sciences, mechanics (anatomy) and chemistry are by far the most important: the study of physiology, therefore, will comprise, according to this view,—1st, a knowledge as perfect as can be obtained of the laws of the living animal economy—laws which, like the living agent itself, are *sui generis*, and only comparable with one another; 2, a knowledge of general anatomy, or the mechanism by which the living agent operates, and is, in short, manifested to us; and 3, a knowledge, as far as can be obtained, of those important chemical changes constantly going on in the living animal, and apparently necessary to its existence. Now, though these two latter branches of knowledge throw no light whatever upon the abstract nature of the living principle, or even of its laws of action, yet, like the index to a complicated piece of mechanism, or the chemical action of a galvanic battery, they often enable us to influence, and even regulate them to a very considerable extent, in an indirect manner; and, in fact, they constitute our only legitimate and rational means of doing so.

4. The next point which I deem it necessary to notice is Dr. Philip's opinion on the nature of the nervous principle. "Does Dr. Prout, then, consider the term nervous and living principles as synonymous? Principles that have not one quality in common?" To which I answer, that I *do* consider the nervous principle to be a living principle, and beg to ask who besides Dr. Philip does not? Indeed, what the doctor meant in this place I was for some time at a loss to comprehend, till

I recollected that he entertained some whimsical notion that the nervous principle was identical with galvanism—a notion which I not only do not admit, but have always considered as absolutely absurd. Let us examine this matter a little.

It is a remarkable feature in all Dr. Philip's observations, that *words* rather than *things*, seem to occupy his mind. This is particularly the case with the word galvanism, or electricity, which he seems to consider as representing some abstract agent or energy, uniform in its character and effects; instead of viewing the *thing* galvanism as it really exists—that is to say, as consisting of two distinct but inseparable energies, directly opposed to each other, which so far from being capable of being substituted for one another, or employed indiscriminately, act directly contrarily, the one invariably undoing what the other does*. From these well-known properties of the galvanic energies, in all experiments made with them, it becomes necessary, in the first place, to consider the object we have in view, and to arrange the polarities accordingly, otherwise, so far from accomplishing our object, we shall do just the reverse. Now I cannot find that Dr. Philip in his experiments with galvanism on living animals, has at all taken this important point into account; whether, for example, the action of the nerve he operates upon be positive or negative; nay, I do not observe that he even alludes to the subject, but seems to consider it a matter of perfect indifference whether (supposing, for example, the action of the 8th pair of nerves be positive) he attempts to supply its nervous influence from the positive or negative side of his battery. Now this has always appeared to me to constitute, at the very outset, a fatal objection to the doctor's conclusions; but there are other objections, if possible, still more formidable than this. Let us suppose, for the sake of argument, that the action of the 8th pair of nerves be positive, and that at the termination of the nerve in the stomach it forms a union, or state of equilibrium, with its opposite or negative energy, the galvanic circle will thus be completed within the limits of the animal's stomach and the nerves

* For the sake of easier illustration, I adopt the hypothesis of two energies; but the objections are equally valid on the Franklinian hypothesis.

supplying it, or, at least, *within the body* of the animal. Now let us consider how the doctor completes his substituted galvanic circle, after the division of the said nerve. We shall suppose that, by accident, the positive wire of the battery is attached to the divided end of the nerve (supposed to be positive), and that thus a current of positive electricity is sent along the course of the nerve—what happens then? *Instead of terminating in the stomach*, like the nervous energy for which it is substituted, it is directed on through all the intervening muscles, integuments, &c. to the *outside of the animal's body*, and is then connected with a train of wires to the other end of the battery. Now I appeal to any one acquainted in the least degree with the principles of galvanism, whether the two cases can be considered as similar, and whether, supposing the nervous influence to be galvanic, and the polarity even to be rightly adjusted, the galvanism supplied can be considered as acting identically with, and therefore forming a proper substitute for the natural action of the nerve.

But, leaving this part of the subject for the present, let us view the matter in another light. The galvanic energies, as we understand them, are not cognizable to our senses in that state of equilibrium in which they are supposed to exist every where, and only become known to us when this equilibrium is destroyed. Now let us suppose them to exist in a state of equilibrium in the nervous system of a living animal, and some occasion arises for galvanism in an active state, to obtain which, of course, the assumed state of equilibrium must be destroyed. How is this to be effected? The galvanic energies have not the power of destroying their own equilibrium; and if this be done at all, therefore, it must be done by a power existing in the nervous system different from these energies, and superior to them. Nor is this difficulty got rid of by supposing, as some have done, that during the life of an animal, the galvanic energies are always active in the nervous system. Every body knows that they are not always *equally* active; and as we can no more suppose them capable of regulating their own activity, than of destroying their own equilibrium, we are still driven as before to the necessity of supposing the existence of a su-

perior principle. Now this superior principle, whatever it may be, residing in the nervous system, ought, I think, to be considered as the real nervous principle; and as it exists in the nervous system during the life only of the animal, it ought to be considered as a living principle: for I need scarcely observe, that the galvanic energies exist in the same state of equilibrium in the *dead* animal as we supposed them to do in the *living* one, but their equilibrium can no longer be destroyed, even though the nervous apparatus remains quite perfect, because the proper living nervous principle no longer exists.

Several other difficulties with respect to the doctor's opinions might be pointed out, if my time admitted; but I presume what has been said is quite sufficient to shew how very ill grounded they are; I hasten therefore to consider the point alluded to in my last letter, viz. the doctor's notable project of supplying artificially, in various diseases, the nervous principle, by sending a current of galvanism through the body; and I do this at the risk of being considered guilty of a little tautology, with the view of preventing others from falling into a similar absurdity. Let us suppose the disease to be asthma, and that, according to the doctor's notions, the nerves influencing the lungs in this disease be deficient in action, and that it is intended to supply artificially this deficiency by its presumed equivalent, galvanism; how is this to be effected?

"Two thin plates of metal," says the doctor, "about two or three inches in diameter, dipped in water, are to be applied, one to the nape of the neck, the other to the pit of the stomach, or a little lower. The wires from the different ends of the battery (containing from eight to sixteen four-inch plates of zinc and copper) are brought into contact with the plates, and as great a galvanic power maintained as the patient can bear without complaint. In this way the galvanic influence is sent through the lungs, as much as possible in the direction of the nerves; and" (mark this particularly) "*the relief seems to be the same whether the positive wire is applied to the nape of the neck or the pit of the stomach.*" Now the nervous principle acting in the lungs, supposing it be common galvanism, must be positive or negative, at least *it must move in one direction*. The doctor applies the poles

of his battery indiscriminately, and thus *reverses the current at will*, and, wonderful to relate, *the same effects take place*. In the patient the entire galvanic circle is completed *within the body*; the doctor's substituted galvanic circle is completed, under totally different circumstances, *without the body*, the body forming only a small portion of the circle. The simple statement of these facts, as before observed, are quite sufficient to satisfy any one acquainted with the principles of galvanism of the absurdity of the doctor's conclusions; and not only this, but even to shew that the *agent employed* by the nervous principle can hardly be considered as *identical with galvanism*, as we are acquainted with it.

With respect to the point under consideration, my own notion on the subject (formed now nearly twenty years ago,) is, that the galvanic energy, (or energies) in some state or other, is *employed as an agent* by the nervous principle; though I never have been able to form any probable notion as to the mode in which this is effected. From the beginning I have been puzzled to dispose of the polarities; it is very easy to suppose that a given nerve acts positively, but then how is the other polarity to be disposed of, (for every body knows, as before observed, that in galvanism, as we are acquainted with it, the positive energy cannot exist without its corresponding negative, and *vice versa*); do the different energies exist in a different set of nerves, or in the same nerve—that is to say, are there two currents, the one of positive and the other of negative electricity, in every nerve? On account of these, and other difficulties that might be mentioned, I long ago came to the conclusion, that the galvanic energies existing in the nervous system of animals could not be exactly identical with those we are acquainted with; and the experiments of Davy and other philosophers, seem, in my opinion, to satisfactorily prove this. Probably the galvanic agents, as they exist in living beings, have the same relation to matter in a merorganized condition, that common galvanism bears to matter in its pure or homogeneous state. The subject is one of great curiosity and importance, and, in the hands of a master like a Wollaston or a Davy, would, I have no doubt, lead to the most unexpected results.

Lastly, I by no means wish to be understood as denying the results stated by Dr. Philip as happening in his experiments; nor do I doubt the efficacy of galvanism in various diseases, but, on the contrary, think rather highly of it when judiciously applied. Were it necessary, these might all, perhaps, be satisfactorily explained on principles very different from those assumed by Dr. Philip.

5. The objection in the last paragraph of page 738 is too subtle for my poor understanding; if it has not, therefore, been already replied to, I must be content to leave it to its fate.

6. The objection in the next page is founded principally on an accidental error. Instead of "merely," I wrote, or intended to write, "chiefly," as might indeed have been inferred from the context. I give the doctor the full advantage of this slip.

7. I pass on now to the next paper, and the first point I arrive at is the doctor's remarks on the term "merorganization." His objections to this term, as far as I can understand them, are two-fold; first, as a mere chemical term, "because it implies a knowledge of different degrees of organization;" and, secondly, as a physiological term, "because it involves me in considerable difficulty." Let us inquire a little into these points.

With respect to this term, I have stated, in a quotation given by the Doctor, that it is used "*provisionally, and to prevent circumlocution**," to express a very numerous set of phenomena apparently connected with the presence of minute portions of foreign bodies, some how or other associated with bodies formed on definite principles; and that these phenomena, if not absolutely identical with those of organization, at least appear to constitute their ground-work—that is to say, that organization cannot exist without the presence of these foreign bodies. As to the term itself, therefore, this will of course be superseded the moment the doctrine it is intended to designate be established or refuted; for, in the former case, the old term, organization, must necessarily convey the same meaning, and in the latter it will of

* And I may add, to prevent the necessity of giving a new meaning to the simple term organization, by encumbering it with what must be considered at present as an hypothesis.

course become superfluous. The term, therefore, in this general sense (or the old term organization, if any one prefers it,) necessarily includes a vast variety of phenomena differing from one another, not only in degree but in kind. My opponent, however, (still doomed to be the slave of a word) will not, as far as I can understand him, admit that organization *does* differ, either in kind or in degree; and upon this assumption his objections are chiefly founded. But he must speak for himself. After alluding to the different senses in which the term has been used, and observing that it sometimes expresses the composition of dead as well as of living animal and vegetable substances, he observes, "In this latter sense of the word, the more perfect animals, I conceive, *have no organizing power*—they can only exist in matter already organized;" and "if the more perfect animal was capable of organizing its food, like the vegetable, or, as it would appear, some of the more imperfect animals, it could live on air and water alone!" The more perfect animals, says the Doctor, have no organizing power. Does, then, the man who dines off potatoes, and converts them into human muscle, not further organize, or at least differently organize, the already organized potatoes? Does the organization of the zoophyte not differ in kind or degree from that of the human being?

Again, I have said, speaking of the merorganizing power of the stomach, "From long attention to the subject, I am satisfied that the merorganizing principles are chiefly derived from the living animal itself, *at least the more essential ones*, and that they are contained in those products of secretion furnished by the stomach and other organs." The Doctor here cuts short the quotation, but I go on to observe, "the merorganizing principles, therefore, already existing in the aliments, though they undoubtedly render them better adapted to the purposes of the animal economy, are not sufficient; and unless the economy furnishes the materials, properly prepared, the future work of assimilation will be imperfect." The meaning of this, admitting the existence of different degrees or kinds of merorganization (which no one can, I think, for a moment doubt), is, I presume, sufficiently obvious; but the Doctor's observations on this passage are really a

curiosity, and as they place in a striking point of view, and in few words, his general mode of reasoning, I shall quote them, for the amusement of the reader. "*If the stomach merorganizes the food, it must have a disorganizing power, because the food is wholly organized when it enters it.* It will be admitted that no organization can be more perfect than that of the muscular fibre."!

The points to be considered with respect to merorganization, and to which I particularly wish to direct the attention of the physiologist, are, can or cannot, or rather does or does not, organization take place without the presence of these foreign bodies; and if so, under what circumstances? How is merorganization, in its simplest state, connected with *isomerism*? Had Dr. P. instead of quibbling about the use of the term, directed his attention to these points, he would have done physiology some service. For my own part, I can only say, after many years attention to the subject, and the investigation of innumerable facts, I have little doubt upon the subject; but I must leave the matter now to be confirmed or refuted by others.

6. The next point considered by Dr. Philip is, "how far chemistry is applicable to explain the phenomena of the living animal." And here, instead of keeping to the point in question, he gets as usual quite beside it, and brings forward such a mass of common-place and irrelevant matter that it is quite sickening to wade through it. The clue to the whole, as far as I can understand it, is, that what I do not happen to mention in my lectures, I either am quite ignorant of, or call in question, or actually deny; and by the aid of this clue, and a few illustrations, the reader will be enabled to get a little insight into the affair.

a. "Physiology and chemistry will always be regarded as distinct sciences, and the circumstance of the same person studying both sciences, will not form these sciences into one." I am perfectly aware of this, and have nowhere asserted the contrary. I have, indeed, spoken of the study of the anatomy, of the chemistry, and of the living functions of animals, as coalescing or constituting one great whole—viz. general physiology—and also of the physiologist turning chemist; but these are quite different things.

b. "To be thoroughly acquainted with the vast science of modern chemistry, and keep pace with the rapid discoveries which every day add to its utility and importance, he must make it his chief business, to the neglect of what more particularly belongs to his own department." A simple and obvious truism, but quite misplaced here, as it had never been called in question. The physiologist has no more to do with the vast science of modern chemistry in all its details, than he has to do with building steam-engines, or any other engines. Inorganic and organic chemistry are quite distinct branches of the science, and an individual may excel in one and know little or nothing of the other. In short, I should say that there is no one more liable to fall into errors than the mere inorganic chemist, when he comes to operate for the first time upon organic substances. I found this, from experience, fifteen or sixteen years ago, and was induced to relinquish general chemistry very much in consequence, since which time I have had little to do with minerals except those of the commonest kind, or those employed in pharmacy, with which every body is supposed to be acquainted. I will venture, however, to assert, whatever the doctor may think of the contrary, that, in the present state of physiology and pathology, a knowledge of organic chemistry, and its rational and cautious association with the phenomena of life, is absolutely necessary to him who wishes to become thoroughly acquainted with his profession; and that he who neglects it, neglects one of the most powerful, and in many cases, the only means of acquiring accurate knowledge.

c. "In speaking of the phenomena of animal life, Dr. Prout keeps in view only the chemical department."—"Now chemistry is powerless in investigating the laws of the vital functions, and ever will remain so." My object was professedly to speak of the application of chemistry to physiology and pathology: I had, therefore, nothing whatever to do with the other departments of the science, or, at most, occasion only to mention them incidentally. Besides, I was addressing an audience supposed to be already well acquainted with these matters. Had I been writing a professed work on physiology, of

course every part of the subject would have been equally treated of. If I am to be blamed, however, for this omission, is not Dr. Philip much more deserving of blame, who has written a book professedly on the vital functions, and yet has omitted entirely the chemical department of his subject? To the second part of the above objection, I reply by quoting my own words, "The only way in which a physiologist can hope to influence the operations of nature, is *through the indirect agency of those circumstances which naturally possess the power of influencing them*, and the management and control of which are, to a certain extent, within his power;"—and "*the laws of the animal economy will never be explained by chemistry, or by any other means.*"

These observations apply equally to the next four paragraphs, the whole of the objections in which are founded on the erroneous assumption that I am ignorant of, or neglect the other departments of physiology, because from the nature of my subject I am not led to mention them.

d. Dr. Philip next attacks what I have said on the powers of chemistry, when sufficiently understood and rightly applied, of "directing the physician generally what to do and what to shun;" and after stating a variety of objections quite beside the point in question, ends by observing, "Dr. Prout may say, that chemistry will assist in directing his choice of the means by which these effects are produced: undoubtedly it will: here chemistry is in its proper place." But then, (just as if I had laid down the rule, "neglect the laws of the animal economy, and attend only to chemistry") he lapses into the old story, and exclaims, "but of what use would this chemical knowledge have been if the laws peculiar to the animal economy had not in the first place supplied the indication of cure." I observe in his last letter, the doctor recurs again to this point, and places in juxtaposition the above observation, and one in which I have elsewhere said that I do not know a single instance in which chemistry can be *directly* applied to the purposes of the animal economy, as if the two were in opposition to each other. But the fact is quite otherwise. The absurd idea, indeed, never entered into my head that chemistry at any

time will never be capable of being *directly* so applied ; but that it will be capable of doing all that I have anticipated in an *indirect* manner, I have not the least doubt.

e. The last point connected with this part of the subject which I think it worth while to notice is, "what opportunities has the chemist of ascertaining the numberless chemical changes which take place in disease : can he operate on the internal organs and their juices as in an animal or vegetable product separated from the organic body which produced it?" When Dr. Philip made these remarks he was evidently thinking of the pots and crucibles, and clumsy chemistry, of a former age. And, indeed, it is evident, not only from this, but from the whole tenor of his remarks, that he is totally unacquainted with the refinements and resources of modern chemistry, particularly as regards its application to organic matters.

7. I come now to the last part of my opponent's observations, "the application of chemistry to the treatment of diseases;" and here as before, he is radically wrong from beginning to end. The clue already given may be here applied pretty much in the same manner as before ; I shall, therefore, think it necessary to notice only a few of his remarks.

a. "Dr. Prout forgets that the chemical changes which take place in the animal body are but the subordinate parts of its various functions, &c." To which I answer that I *do not* forget this. Had the doctor taken the pains to read what he professes to criticise, he would have seen that I allude to chemistry as a means of enabling us "to associate the fleeting phenomena of disease with the more tangible and intelligible phenomena of matter," but not of directly suggesting remedies for them. The phenomena of disease I study like the doctor or any other individual, and the only difference between us is, that I associate these phenomena with chemistry, (in the same way that others associate them with the state of the pulse, tongue, &c.) and as far as I am able, ascertain what deviations from the healthy state of the solids or fluids accompany the symptoms. Now these deviations often present a means of diagnosis infinitely more certain and instructive than all the others put together, especially in dis-

eases of the assimilating functions and certain constitutional affections.

b. "One of the greatest errors of Dr. Prout's pathology is that his principles lead him chiefly to look at the state of the fluids;" and "the tendency of his doctrines is to bring us back to the humoral pathology," and "lead to its worst results." The old idle dispute about solids and fluids, as these terms are understood in speaking of living animal bodies, has always appeared to me to be little better than downright nonsense, and to be founded in ignorance of the real nature of the subjects of dispute. What sort of a *solid*, for example, can we conceive that to be which, like a piece of muscle, contains upwards of seventy-seven per cent. of water? And by how much can it differ from the *fluid albumen ovi*, which contains only three per cent. more? And besides, do we not see that all the phenomena of life can be equally associated with the *fluid albumen* as with the *solid muscle*? Solidity and fluidity, speaking with reference to living products, have reference chiefly to some mechanical object, (e. g. the *fluid blood* to circulate in tubes—the *solid muscle* to move an inflexible lever, &c.) and have little or nothing to do with the mere circumstance of life, which can be equally attached to both states. Indeed, both states are equally necessary to the existence of the animal economy ; and were we to judge from various circumstances, and particularly the mere quantity, we should be inclined to think the fluid state was the most important of the two. Lastly, in a chemical point of view, in examining an animal product, the mere fluid or water is put out of the question, our attention being directed solely to the solid matters contained in solution in it. As to the *tendency* of my doctrines, I shall only say, if they are *true*, there is no fear of their leading to *error*.

c. In speaking of diabetes, Dr. Philip says, "I have within the last twelve months had the satisfaction to see a case of diabetes mellitus cured, and as far as I know, permanently, by *minute mercurial doses*, combined with other means of strengthening the digestive organs, but none of these means had any relation to the state of the urine." Had Dr. Philip given us the specific gravity of his patient's urine *before* and *after*

the said cure, some judgment might have been formed on the point. As it is, he may be assured that no one who knows any thing of diabetes, will for a moment attach the least credit to his history, at least I do not. As to the insinuated *cui bono*, (of what use is a knowledge of the state of the urine, when I can cure this and half the diseases of humanity with a little blue pill?) this is just what might have been expected from my opponent.

d. Dr. Philip terminates his observations by saying, that "the tendency of chemistry is to narrow our views of the animal economy, and lead in pathological reasonings to a neglect of the laws peculiar to it." Putting out of view the paradox contained in this observation, that what increases our knowledge is calculated to narrow our understanding, the general argument, if it has any weight, applies with double force to the man who confines his attention principally to the metaphysical portion of the economy he has to deal with, to the neglect of the physical and chemical.

I have now done with this subject, which I must leave to its fate. That my opponent, like all men of words, will have the last word, I have little doubt, but without some extraordinary provocation, it is not my intention to notice what he says. The controversy has ended like most controversies do, by probably convincing neither party, at least, I am sorry to say, this is the case with me. Dr. Philip has, indeed, talked largely of errors, &c.; but I think I have shewn that in general they have all been of his own creation, or have had no existence but in his own imagination; and after due consideration, I cannot admit that a single fact, or even opinion, has been shaken by any thing he has advanced. With respect to the feelings under which my former notices of his observations were made, I can assure him that they were not those of pride or of anger, as he supposes, but of something very different. It has been a rule with me through life never to attack any human being; but when I am attacked, and it becomes my duty to defend myself, I do this as well as I can; and on such occasions never hesitate to speak my mind. If the doctor, therefore, has got himself offended in this matter, he has to thank himself; for when he so far for-

gets what he is about as to make an attack upon me a pretence for bringing forward his own discoveries; when he advances paradoxes, and quarrels with me for not understanding them; when, instead of fair criticism, he brings forward all sorts of irrelevant charges; I say, when he does all this, can he reasonably expect to be "spared" from certain expressions of ridicule or contempt which such a mode of proceeding is calculated to call forth, and which he so feelingly describes in his last letter, as being so "melancholy to witness?"

W. PROUT.

Sackville-Street, Oct. 7, 1831.

CHOLERA.

To the Editor of the London Medical Gazette.

Exeter, October 1, 1831.

SIR,

I PROPOSE, with your permission, to submit to your numerous professional readers some remarks which tend, I think, to illustrate the mode in which *cholera* may, with most probability, be supposed to be propagated. You have, with great propriety, made it an especial object in your late numbers to put the public in possession of the best information in relation to this painfully interesting subject, both in regard to the facts of the case and the opinions which are to be deduced from them; and this being your avowed design, will serve me as an apology for placing the following thoughts at your disposal.

In a general view, epidemic diseases may be supposed to be propagated or diffused in one of the three following ways. 1. By corruption of the air, breeding a *morbific aerial poison*, independently of the contagion of previously existing disease. 2. By *contagion*—that is, the reception into the persons of the healthy, whether by *contact* or *otherwise*, of morbid poison generated in the persons of the sick. 3. By the union of both these modes, when the original corruption of the air engenders in human beings a species of disease which, being thus engendered, is afterwards capable of propagating itself by

contagion. Some further variations of circumstances may be imagined, as, for instance, that of a reciprocal infection of the air itself from the persons of the diseased; but as I am not writing a professed treatise on the subject, the distinctions made above will be sufficient for my present purpose.

1. If the corruption of the air in any case be that of the *atmosphere at large*, it must be inferred that such corruption will inflict disease *almost simultaneously* on a number of individuals throughout a large tract of country. I am not aware that such a result accords with experience in the history of any epidemic.—The late influenza spread as rapidly and extensively as perhaps any disease on record. Yet in this the affection was often found prevailing in one town or village many days, or even some weeks, before it commenced its attacks in others not many miles distant. This fact seems clearly to indicate that the state of air which so affected individuals was *local*; and that it did not exist, at least not in such intensity, as to be capable of producing the disease throughout the *atmosphere at large*. As respects the cholera, it is evident that its progress is much slower than that of the influenza, and therefore can still less be supposed to be immediately produced by a *general* corruption of the atmosphere. As far, then, at least, as regards diseases of this character, if they are to be accounted for by the supposition of a poisonous air, we are driven to the hypothesis of such a state of the air being *local* or *partial*, and at the same time spreading by a certain progress from place to place. Now such local corruption of the air in epidemic diseases may be referred to one of two causes, according as we suppose it to be always originally generated in or near the spots where it exists, or to have infected those spots in consequence of a spreading contamination derived from other neighbouring places. In the first case, setting aside the idea of mineral exhalations, we must ascribe the unusual local production of aerial miasma to something peculiar in the general constitution of the seasons or of the atmosphere. This hypothesis seems well fitted to explain the extraordinary prevalence of intermittent and remittent fevers in certain seasons, in districts infected by marsh miasma. But it does not appear to meet the case of a disease which,

like the cholera, is found to spread by a gradual and regular progress, over a varied and extensive range of country, and through a succession of seasons.—Putting, for the present, the hypothesis of contagion aside, I am at a loss to conceive of any probable mode in which such a disease can be supposed to be propagated, except that of a progressive contamination of the air itself, creeping onward with varying measures of force and velocity, and in varying directions, according to local circumstances, from place to place. If asked on what principle I propose to explain this progressive contamination, I should answer, that it may be explained by supposing some process to take place in the air analagous to *fermentation*. I should not suppose such a process to exist among the proper elements of the air itself, but in the stratum of animal and vegetable effluvia, which, though invisible, unquestionably exists in a state of solution or suspension, in the portion of the atmosphere which lies next the earth. And as these matters, in kind and in concentration, must greatly differ in different spots, and therefore may be supposed to present the requisite materials for the peculiar fermentative process in one place more than in another, we see a reason why the disease thence arising may be found taking an irregular and seemingly capricious rout, and especially why it may manifest itself with deadly virulence in large and ill-conditioned towns, while it spares its neighbouring country. Moreover, the manner in which cholera develops itself, generally attacking great numbers, and with fatal violence, almost at its first onset, and then declining and finally disappearing in a given place after a few weeks, seems well explained on this hypothesis, as a fermentative process would naturally proceed in this manner. Nor can I conceive in what other way the sudden transition of a town from a state full of disease and death to one of health, while in the meantime a neighbouring town has experienced a change exactly the reverse, can be explained.

Supposing the foregoing hypothesis to agree with reality, will the cholera reach our own country? This interesting question I think we have not the means of deciding. A fermentative process in the air might extend itself to us in two ways. The engendered poison might be *wafted* over to us, and might

proceed to leaven congenial spots on this side of the water. For although experience seems to teach us that the air of the open sea never contains the choleric poison in such intensity as to induce the disease in a man previously uninfected, yet that is no proof but that there may be enough of it diffused to act as a leaven on the land air of an island to which it may be carried.— Nevertheless, the supposition of the seeds of this fermentation being so extensively diffused, seems to be negatived by the slow actual progress of the disease, which in such a case could hardly fail to have been diffused by the easterly winds over the whole of the continent long ago. Another supposition is, that the stratum of air across the channel may itself be capable of taking on the fermentation in a sufficient degree to propagate it to our island, although not infecting those on the sea with such a dose as to induce disease. The observation of facts alone seems capable of deciding this question; and we are not, I believe, at present in possession of any which are sufficient for this purpose.— The disease has not yet crossed the Baltic to Sweden, it is true; but the Baltic is much wider than the straits of Dover; and what was the fate of Ceylon in India? If I rightly remember, it was not exempted. Unless, however, the hypothesis of contagion were absolutely negatived, this fact would not be of much weight. On the whole it seems to be rather a forlorn hope, should the cholera reach the opposite shores of the channel, that that narrow sea will be sufficient to arrest the progress of an aerial contamination which has taken so extensive a range. Notwithstanding, it cannot be denied that so happy a circumstance is *very possible*, and that our efforts to avoid the importation of that disease in another manner, ought not, therefore, to be relaxed.

2. This leads to the consideration of the second mode in which I observed that an epidemic might be propagated: namely, contagion. On this point, however, it is not, at present, my intention to enlarge: it is evident that the question of the contagiousness or non-contagiousness of cholera, is one on which those who have had the best opportunities for observation, have found it difficult to arrive at a satisfactory conclusion. In the meantime, however, we may observe, that it is one thing to

maintain the contagiousness of cholera, and another to maintain that the disease spreads, principally or entirely, by virtue of that contagiousness. I am inclined to think that but few well-informed medical men incline to the latter opinion, however they may be disposed with respect to the former. In India, certainly, the contagiousness of cholera was much less thought of than it has been in Europe; but it seems to me not an improbable explanation of this fact, that the disorder may be contagious in the stage of febrile re-action, though not in its first stage of coldness and depression; and as the febrile stage appears to have been much more strikingly developed in the European epidemic than it was in India, such a difference in the experience of the two regions would be a necessary result. Add to this the well-known fact, that in India contagious typhous fever is a disorder which hardly occurs. If cholera is contagious, it is in all probability only *as a fever* that it is so; but on the other hand, as all other epidemic continued fevers have been found in one latitude to possess a contagious power, there appears a considerable presumption for the opinion that cholera, when assuming this form, may possess such a power likewise; and I think there is much in the statement of the facts which have been transmitted to us which would tend to confirm this opinion.

3. An epidemic, spreading both by corruption of air and by personal contagion, is probably a common form of disease, while it affords an occasion of interminable controversy to those systematists who cannot enlarge their views so as to embrace more than the one or the other of these hypotheses exclusively. I have already intimated an opinion that cholera is, in Europe at least, a disease of this description; for however disagreeable it may be to entertain a conviction that our dreaded enemy is thus provided “with two strings to his bow,” it appears to me that the history of its progress is best explained on that supposition. Admitting, however, the probability that the *fever* of cholera may be more or less contagious, I would by no means advocate an opinion that such contagiousness is the principal cause of its progress, inasmuch as the detailed history of its progress does not appear at all to coincide with such an hypothesis. So far from it, that the

cholera does not appear capable of supporting itself in a given place more than for a very short time ; so that, whether contagious or not, we are almost constrained to believe that a local corruption of the air must in all cases be necessary to its popular diffusion. Unless, therefore, that corruption of the air should previously have extended across the sea to this country, it seems very questionable whether, even if imported, its contagion would be able to diffuse itself among us ; unless, indeed, the miasma from the patient be in itself capable of acting as a leaven of corruption to the air.

Should you deem the foregoing remarks deserving insertion in your excellent journal, you will gratify

Your constant reader,

T. F. BARNHAM.

CHOLERA IN TURKEY.

To the Editor of the London Medical Gazette.

117, Crawford-Street, Portman-Square,
October 1, 1831.

SIR,

THE enclosed is extracted from a letter received a few days ago from Constantinople ; the writer being non-medical, a member of a mercantile firm.

Yours most respectfully,

THOMAS BUSHELL.

The cholera had spread very considerably soon after the 10th instant, varying, however, very much in its force and effect in different situations, and had proved very fatal in all the low and confined places, particularly at Galata and Annout Kani on the Bosphorus ; and, perhaps, nearly 200 were taken off per day for several days : the species of cholera is, however, of a much less fatal nature than that of Russia, and when taken in time by bleeding and warm stimulants, the attacks have in few cases proved fatal. At Therapia nearly 200 persons have been attacked by a species of cholera ; but, from the healthiness of the situation, not above 10 or 15 have died : in other places all the inhabitants have fled. Its ravages have chiefly been confined to the poor Armenians and Greeks, and but few respectable Franks have died : among the English, only Mr. Canning has been

202.—IX.

dangerously attacked, (the 13th instant,) and had not immediate medical assistance been procured, he would certainly have been taken off. The symptoms are—headache, vomiting, violent spasms in the stomach, and cold and *cramp* in the hands and feet, and stoppage of the circulation of blood. The attacks come on suddenly, and people fall apparently dead with them in the streets, and are only recovered by immediate bleeding, rubbing of the limbs violently with warm cloths dipped in brandy and vinegar, and drinking warm brandy and water, with about 20 drops of laudanum, and the application of *hot tiles or bricks* to the stomach and feet : a warm bath is likewise strongly recommended when procurable. But in most cases bleeding alone has been sufficient, when done immediately. I believe several people have died from excitement and distress, caused by the fire at Pera.

TREATMENT OF BURNS.

To the Editor of the London Medical Gazette.

North Shields, Sept. 30, 1831.

SIR,

HAVING recently seen Mr. Thomas's Essay on the Treatment of Burns and Scalds, I have been induced to send you an account of the plan I have pursued for several years, which I beg you will insert in your valuable Gazette ; and as it is not my intention to write an essay, but merely to promulgate what I have found to be a most successful mode of practice, I shall be as plain and concise as possible, briefly stating the advantages this plan possesses over other modes of treatment. In the first place, it sooner affords relief to the sufferer, who seldom fails to express the comfort afforded by the application ; secondly, in most cases it heals the burn, however deep, without inducing suppuration, and never gives rise to those contractions produced by the cicatrization of burns : and lastly, the simplicity of the plan itself is no small recommendation.

Having enumerated the advantages to be gained, I will at once proceed to the mode of treatment, which requires a little variation according to the situation of the part injured, as it is necessary, for the full attainment of the objects

E

before enumerated, that the injured parts should be subjected to no pressure. I shall, therefore, begin with burns of the face, which are by far the most manageable of all. Being called, then, to a case where the face is burned either seriously or slightly, I immediately administer hot wine and water, so as to produce as speedy a re-action as possible; and if the burn is deep and extensive, I have the patient placed in a well warmed bed; and having put $\mathfrak{z}\text{i}$. of the ung. resin flavæ, and $\mathfrak{z}\text{ij}$. of the ol. terebinthinæ, in a tea-cup, it must be melted over the fire, and when reduced to a liquid state it is to be applied, like a varnish, with a soft brush or bunch of feathers, over the injured surface; and this is to be continued until the parts are thickly coated, so as completely to exclude the atmospheric air. Care must be taken to renew the coating as often as may be necessary; at first perhaps two or three times a day, but afterwards partially repairing it once a day is all that is requisite; and in this consists the whole of the local treatment. If the burn has been deep, of course a slough has to separate; this will be found to take place, or rather to commence to take place, at the end of from ten to fourteen days, according to the depth destroyed. As it separates at the edges, it curls up like a piece of shrivelled leather, which curled edge may be cut off with a pair of scissors, taking care to renew the coating wherever it is displaced by the edges of the separating slough; and so it will proceed until the whole of the slough has come away, when it will be found that the cure is complete, the parts having granulated and skinned under the slough, which has only separated as that process has been completed. The new skin will be found to be perfectly smooth, there being no contraction of the features; and in a few weeks the face will recover its natural colour, leaving no vestige to indicate that such an injury had ever been sustained.

I shall next proceed to burns of the throat, breast, abdomen, and interior parts of the legs and thighs, in all of which precisely the same plan is pursued, only placing a frame of basket-work over the patient, to prevent the bed-clothes coming in contact with the injured surface, which must have no immediate covering except the application

with which it is coated. In burns of the upper extremities the same sort of contrivance will perfectly answer to preserve the part from even the slightest pressure.

The greatest difficulty to be encountered in following up this plan of treatment is when the shoulders, back, loins, breech, &c. are the injured parts, when, of course, it is impossible to defend them from encountering considerable pressure, and in such case it is impossible to prevent suppuration taking place, to a certain extent at least. The plan I pursue in such a case is, after coating the surface in the usual way, to cover it over with a very thick layer of cotton wool, and so securing it by drawing a sufficiently large cloth pretty tightly around the body; and this should be allowed to remain without removing for three or four days, when the operation must be repeated, unless the oozing of discharge, or a very offensive smell, renders it advisable to open out the part sooner, when it will be found that the suppurating surface will be very considerably less than if dressed in the ordinary way, besides healing in a much shorter period of time.

With regard to the constitutional treatment, as I before mentioned, I always give hot wine and water, or hot brandy and water, so as to induce a speedy re-action, which being once established, the treatment should be strictly antiphlogistic, attending particularly to keep the bowels moderately open, on the one hand, and to avoid too active purging on the other. Castor oil I have found the best medicine in these cases; saline purges I have often found to produce cold shiverings, and a disposition in the injured parts to suppurate.

I remain, sir,

Your obedient servant,

EDWARD GREENHOW.

P.S.—Should the application be found too soft, it is easily remedied by the addition of a small portion of rosin and yellow wax.

ANALYSES & NOTICES OF BOOKS.

L'Auteur se tue à allonger ce que le lecteur se tue à abrégér."—D'ALEMBERT.

Practical Observations on Prolapsus of the Rectum. By FREDERICK SALMON, F.R.C.S. Author of a Practical Essay upon Contraction of the Rectum, Piles, &c.; Senior Surgeon of the General Dispensary, Aldersgate Street.

MR. SALMON finds fault with the usual designation of the disease of which he treats, viz. prolapsus ani, and substitutes for it that of prolapsus of the rectum;—we have no objection. Farther, he protests against the practice of applying ligatures, either here or in piles, and proposes a method of his own. This is the point described, and to this we shall confine ourselves; for we quite agree with Mr. Salmon, that the subject is scarcely fitted for "theoretical ideas and metaphysical reasoning"—metaphysical reasoning about the anus!

The morbid anatomy of prolapsus is first considered; and the reader is reminded that the peritoneum, after it has given an investment to part of the bladder, is continued from the lower and posterior aspect of this organ, to the anterior surface of the rectum, a sort of pouch being formed by the portion of the membrane which intervenes between them. For some short space the peritoneum is continued upon the anterior surface only of the rectum, while higher up it encircles the bowel, and then is reflected to the sacrum. The portion of the rectum which is not covered with peritoneum, is connected with the adjacent parts by cellular membrane only; and thus, while the upper part of the bowel is kept in its proper place by the investment of the peritoneum, and the connexions of this, the lower part is comparatively free, and sufficiently lax to admit of partial eversion. When the rectum is long in a state of irritation, the uniting cellular tissue between the external and internal coats is increased, and the mucous membrane becomes thickened and elongated; and both these changes are usually present when any considerable prolapsus of the bowel takes place. If no means be adopted for its relief, the eversion continues to increase until the entire lower portion of the gut may be protruded. The

causes of prolapsus of the rectum, according to our author, may be either constitutional or local. Among the most common of the former are habitual constipation and diarrhœa; of the latter the most common is a contraction of the gut itself, offering a permanent obstacle to the action of the intestine, and preventing the free return of blood.

The author argues against the employment of ligatures in the removal of prolapsus, and holds, that if the danger of bleeding could be got over, no one would hesitate in giving the preference to excision. The method adopted by Mr. Salmon to accomplish this desirable object, is as follows:—

"The patient having been prepared for its performance in the same manner as for the division of the sphincter, the prolapsus is to be brought in view by the efforts of the individual, promoted by the use of an enema. The sufferer being placed in a convenient position, an assistant separating the nates, one or more of the pins, as may be necessary, is to be passed from above downwards, transversely through the basis of the tumor; these penetrating the muscular coat of the bowel, will prevent the return of the intestine after the diseased part is removed. The pain produced by this part of the operation is insignificant.

"The prolapsus being thus secured, the operator, with the hook or the forceps, is to lay hold of one of the prominent portions of the tumor, and to draw it gently towards the opposite side; with one stroke of the scissors he is then to remove the part as deep as the line of division between the mucous and muscular coats of the rectum, the latter of which should be left entire, otherwise a permanent difficulty of relieving the bowels will follow the operation. In like manner all the protruding portions of the prolapsus are in succession to be taken off."

And again:

"If any material bleeding occurs it is to be checked by the means generally used for stemming hæmorrhage, such as cold or astringent washes. In most cases the flow of blood, which it is better to encourage to a certain degree, will cease spontaneously; but if we are compelled to apply any ligature, it may be done with facility, as, while the pins remain in their situation, we have a commanding view of the parts.

"It is my custom to leave the pins

in their place for an hour or more after the operation, or the cessation of hæmorrhage, to permit the blood to coagulate in the extremities of the divided vessels, by which we prevent any recurrence of bleeding after the bowel is restored to its natural situation. Having removed them, the surface of the divided part should be smeared with sweet oil, and the rectum returned within the sphincter in the gentlest possible manner.

"The after-treatment of the case is usually simple, requiring only that the patient be kept in a state of perfect quietude, and supported upon the most sparing diet, of a liquid description; so as, if possible, to avoid the necessity of passing any evacuation for the first two or three days. At the expiration of such time, the action of the alimentary canal is to be induced by the administration of a mild purgative, assisted during its operation by an enema."

If any serious constitutional mischief should follow, it is to be met by vigorous treatment; but the author states, that he never knew any formidable consequences to result, when due attention had been paid to the preliminary cautions enjoined.

A Manual of Midwifery, or Compendium of Gynæcology and Pædonosology; comprising a new Nomenclature of Obstetric Medicine, with a concise Account of the Symptoms and Treatment of the most important Diseases of Women and Children, and the Management of the various Forms of Parturition. Illustrated by Plates. By MICHAEL RYAN, M.D. Member of the Royal College of Physicians in London, &c. &c. Third Edition. Price 12s.

WHEN the first edition of this work appeared, now some three or four years ago, though we smiled at some parts of it which savoured of the ridiculous, we yet declared it "to contain a great deal of information." We observe that much of the absurdity is retained, as regards the attempt to introduce a set of Greek words—as *gynæcophysiology*, *geneosology*, *encyonatalogy*, *chiragotocia*, and fifty others which are not, and we trust never will be, in use. It is evident, from the *naïveté* with which the author speaks of a journalist who praises him as "the first and best of medical reviewers in exis-

tence," how highly he prizes commendation; and they who do so are, for the most part, equally galled by censure. Having, therefore, on the occasion above alluded to, been more severe than is our wont, we shall not add a word of reprehension now. Nay, to do Dr. Ryan justice, there is more information on the subject of midwifery and female complaints, in the Manual before us, than in any other work of three times its size to which we can refer. This is no mean recommendation, and we are satisfied that it is no more than is deserved.

The elementary nature of the work renders it wholly unfit for analysis. Towards the close of the volume there are a good many typographical errors*.

Reports of Medical Cases. By DR. BRIGHT. Price 9l. 9s.

[Continued from page 16.]

Inflammation of the Membranes of the Brain.

WE resume the instructive and agreeable task of analyzing Dr. Bright's recent work; and the next subject which presents itself to us is arachnitis, with effusion into the ventricles. Cases are given in which this combination ensued, both where the inflammation had come on suddenly, and been rapid in its progress, and where it had been slow and insidious: under both circumstances convulsions, paralysis, passing the evacuations in bed—in short more or fewer of the symptoms regarded as indicative of pressure, manifested themselves. In one case, where the patient was thirty-four years of age, and laboured under symptoms indicative of commencing effusion, of a very formidable kind too, a cure was effected under the use of repeated blistering on the nape of the neck, and a grain of calomel every night for five weeks.

From these the transition is easy to

Cases illustrative of Hydrocephalus.

The two first cases are examples of this disease resulting from blows. In some of those which follow, the evidence of inflammation, as adduced either from the symptoms or post-mortem examination, is of a very equivocal de-

* As this sheet was passing through the press, we received a note explanatory of the circumstance alluded to; the errors are to be corrected in the rest of the impression.

scription. Irritation, in the opinion of our author, is sufficient to cause long-continued irregularity in the muscular actions of the body, and may possibly even give rise to effusion—more especially in those predisposed to hydrocephalus. In several of the cases there would seem to have been effusion, though the patients ultimately recovered; and these favourable results followed very moderate local depletion, cold lotions to the head, and small doses of calomel, with chalk, soda, or ammonia, internally.

The twenty-fifth case is a curious one. A child, twenty months old, who had been observed to have what was thought a trick of knocking his head against persons or objects of any kind, suddenly awoke screaming dreadfully, and appearing to have pain in the head. Leeches, calomel, jalap, and so forth, were employed; but the case went on, and is detailed at considerable length. Strabismus, occasional convulsions, and so forth, manifested themselves, and the child died at the end of about a month. The appearances on dissection were curious, and may be regarded as indicative of a state of congestion and stagnation in the vessels, rather than of acute inflammation. It should be mentioned, that at the time the child was seized, it had laboured under cough for some days.

“On taking off the scalp, the bone had a transparent look as belongs to the age, and a rather dark colour. The dura mater attached pretty firmly to the skull, and when first seen, the bone being removed, looked distended, as if it had been forcibly pressed upwards. On raising the dura mater, all the larger veins on the surface of both hemispheres running into the longitudinal sinus were seen round and hard, quite filled with yellow-coloured coagulum, as if injected with wax, while the whole vertex was covered under the membranes with dark extravasated blood; this was of a deep purple at the summit, and became lighter and more broken further down the sides; so that an incision made all round, rather above the cavity of the ventricles, took off nearly the whole extravasated blood. The coagulum filled the veins through one or two subdivisions in some parts; and on carefully opening the longitudinal sinus, the whole was full of a coagulum, taking the exact form of the sinus, and becoming firmer the more it was traced backwards; this coagulum was almost entirely fibrin, with a little of the red blood in parts and cavities; it was closely attached

in some of the mouths of the veins where they entered the sinus; but this was on account of the fibrous structure of the internal surface of the sinus entangling the coagulum.

The general surface of the brain where the ecchymosis had not taken place, was so far from being vascular, that it was unusually pale; but those parts of the pia mater which ran between the convolutions near the parts where the veins were obstructed, were red, and apparently vascular. On making a clean horizontal cut through the two hemispheres, a little above the top of the ventricles, a number of small round dark red spots, more venous than arterial in colour, were seen thickly distributed in patches: these were chiefly collected in a close body round the inside of the cineritious substance at those parts where the pia mater was most vascular; and the cineritious matter itself was of a darker colour than usual. In one part on the outside of the anterior lobe of the right side, the brain was completely softened, so that on pressing the finger upon it, it broke down easily, and was immediately excavated, leaving the surrounding part, in which were no red spots, obviously much more firm, and indeed natural, in texture and appearance.

“On examining the brain with a high magnifying lens, it was evident that the round specks were small coagula, and were not contained in vessels; for, in whatever way divided, they always presented the same appearance; nor could any thing further be discovered with a microscope. The vessels from which these little clots of blood had escaped could not even be discovered. The ventricles were distended with several drachms of clear fluid, and the septum lucidum and commissura mollis were so soft as very easily to break down; the membrane lining the ventricles was perfectly healthy, and free from vascularity; the posterior cornua were much distended with watery fluid.

“On exposing the base of the brain, the only remarkable circumstance was, that it appeared unusually free from vascularity, and white; and this was particularly the case with regard to the cerebellum, the cineritious portion of which was soft as well as pallid. The vessels of the base, the basilar artery, and the circulus Willisii, were perfectly healthy; there was near the optic nerves a spot where we perceived about as much puriform matter as would form one or two drops, but we did not discover its origin. In the basis was above an ounce and a half of serum; but some of this had probably found its way during the examination, from the ventricles.”

The next observation which arrests our attention relates to coagulation of fibrin in the veins during life. Two

cases of this kind are given as connected with the preceding; they are curious, and illustrate what is probably a rare pathological condition. As they are shorter than most of the others, we shall quote them without curtailment; indeed, they scarcely admit of abbreviation.

"Elizabeth Larnier, aged 17, had been long labouring under anasarca and ascites, with a pulse constantly accelerated and jerking in its beat, ascribed to disease of the heart subsequent to rheumatism, and to disease of the liver. After long and varied suffering, in which she was excessively reduced, and was in her appearance pallid and exsanguine, she became the subject of pain and tenderness above the left clavicle, where slight swelling was soon perceived, and this in a day or two distinctly to be traced in the direction of the jugular and subclavian veins, which might themselves be felt hardened like cords. The whole left arm became œdematous; her weakness and irritability increased; her pulse became more rapid; and she sunk in about ten days from the first discovery of these symptoms.

" *Sectio Cadaveris.*—The sternum adhered very closely to the pericardium; the two surfaces of the pericardium adhered generally by firm and close adhesions; the heart was large, chiefly owing to the increase of the left ventricle. The edge of the tricuspid valve was thickened, but still the auriculo-ventricular opening was very large; the blood in the cavities was but imperfectly coagulated, but the clots extended into the principal vessels; the pulmonary artery and its valves healthy. The left auricle rather thickened; both curtains of the mitral valve rather thick, but not ossified; one of them was a little contracted; some minute and soft fibrinous vegetations were attached to the edges of both curtains; the opening of the valve was very large. Aortic semilunar valves thickened, and almost cartilaginous at their convex part, so that each valve formed a bulging cup. The left jugular and subclavian veins were plugged up by a firm coagulum terminating abruptly just as they entered the cava; the coagulum was of a yellow white, with isolated portions soft and grumous; the blood was partly coagulated and partly fluid in the axillary and brachial veins and their branches, distending many of the superficial veins; the jugular above the fibrinous mass was filled with dark blood not very firmly coagulated: the coats of the vessels were healthy and smooth. The cellular membrane around the veins firm and semi-cartilaginous, and some of the axillary enlarged. The pleura adhered to the lungs, but not so generally as to prevent considerable effusion of serum; there was some recent inflammation on the right side and lower

part of the lung, and a small pulmonary apoplexy. In the abdomen were found about four pints of straw-coloured serum; and numerous old adhesions of the diaphragm to surrounding viscera. Liver contracted and firm, with an irregularly-indented surface. On the uterus was a small attached cyst. Kidneys large and healthy.

"Elizabeth Mucklow, aged 22, was admitted into Guy's Hospital in the month of December, under the care of Dr. Addison, eleven weeks after parturition, during which she had suffered from excessive hæmorrhage. She was pale and bloated, with a sharp jerking pulse, sometimes rising to 140 beats in the minute; she complained of some pain and swelling above the left clavicle, where the hardened veins were distinctly to be traced, as in the last case: the arm became excessively œdematous; and she had not been in the hospital above a week when she died almost suddenly; for though she had been from the beginning much oppressed, she had appeared relieved, and had expressed herself very cheerfully within an hour or two of her death.

" *Sectio Cadaveris.*—On examination, a firm white fibrinous coagulum, almost as hard as cartilage in some parts, was found plugging up the subclavian vein, and this extended two or three inches up the jugulars; it became thin, and more slightly attached to the inside of the vein quite at its entrance into the cava, where it ceased. All the valves of the heart had upon their edges small fleshy deposits of fibrin from the blood, forming fringes of vegetation attached with considerable firmness, so as to allow of being handled pretty roughly without being detached.

"The right auricle of the heart was distended with blood; some fluid in the pericardium; a considerable quantity of serum in the cavities of the chest."

Dr. Bright, after these cases and remarks—which may be looked upon as a kind of digression—proceeds to make some general observations on the treatment of hydrocephalus. He states, in conformity with general experience, that some degree of inflammation will usually be found to have existed, and that it is upon the earliness of the period at which this is discovered, and the readiness with which it yields to depletion, that the chance of recovery depends. But our author urges strongly, that the practitioner should not confine himself to this very limited view of the disease; nor wantonly repeat bleedings, though small, till the powers of life be exhausted. When the little patient begins to be worn out, and sometimes even in the

earliest stages, the depression and irritability are such as to require nourishment and sedatives; of the latter, Dr. Bright prefers tincture of opium, or the liq. opii sedativus, in doses, of course, proportioned to the age of the patient. He has seen four drops of laudanum given three times a day to a child two years of age, "with the best effect." The circumstances, however, were urgent, and the dose is not adduced as an example of what is generally proper. As to the treatment of those cases in which congestion is present—provided this fact could be satisfactorily ascertained during life—rather rapid, but limited, local depletion (as by cupping glasses), and the occasional sudden, but interrupted, application of cold, are suggested, with repeated blistering on the neck. The manner in which mercurials have been used in hydrocephalus is spoken of with disapprobation, as too indiscriminate, and as frequently productive of great irritation of the bowels, and sympathetic disturbance of the head. He recommends their combination with opium.

The author next directs our attention to the effects upon the brain of an inflammatory character, produced by inflammation of other parts, or by general febrile disturbance. Several cases are detailed in which cerebral disease of an inflammatory character appeared to be the consequence of diseased intestines in fever. Several cases are also given where this followed peritonitis; one where it followed erysipelas of the lower extremities; and another where it came on in scarlatina. Another source of inflammation of the brain, in a distant organ, is found in the liver; and various instances are detailed in which hepatic disease, existing with an imperfect discharge of its functions, gave rise to inflammation of the membranes of the brain.

Erysipelas of the Head and Face.

The last set of causes of inflammation about the brain pointed out by Dr. Bright, is disease of the external parts of the head. Erysipelas of the face and scalp constitutes a familiar example of such combination; and the doctor takes occasion to favour us, *en passant*, with his opinions on this disease. He strongly, and we think very justly, protests against the early use of stimulants, or, in fact, any unbending routine practice. He dislikes cold ap-

plications, and favours blisters to the neck; but what he most commends is Dr. Hobson's plan, of making a great number of minute punctures, which our author regards as one of the greatest improvements in modern medicine. The plan is thus described:—

"This consists in making fine punctures, in number amounting to several hundreds, or even thousands, with the point of a lancet over the whole inflamed part; then fomenting with warm water in a sponge, to encourage the bleeding; and repeating this operation two or three times in the twenty-four hours, if the parts look red or tense. If done early, it shortens the disease; but at all events it relieves the vessels in a manner which nothing else in my experience has effected. This remedy was unfortunately adopted too late in the fatal case I have just related: but I will insert the notes of a few cases, which are only a small part of those where I have either tried it myself or seen it tried by others."

Ten cases are given in illustration; we must limit ourselves to two.

Erysipelas of the Head during convalescence from Pneumonia.

"Juliana Pate, aged 26, was admitted under my care on the 30th of June, 1829, with pneumonia, from exposure to cold and wet, which was completely removed by bleeding, leeches to the chest, and the solution of tartrate of antimony. When convalescent, on the 19th of July she was attacked with erysipelas of the face, beginning on the nose and spreading over the whole face and scalp. On the 23d the affection was extensive; and from its attacking the lining membrane of the nose and fauces, and coming on in a patient much reduced, it bore a formidable aspect. I ordered the whole of the inflamed parts of the scalp and forehead and face to be punctured twice in the day with the point of the lancet, and to be fomented. The relief given was very marked: the delirium, which had already come on, was checked, and the inflammation subsided; the punctures were repeated the following day, with the same good effect. A day or two after, it was requisite to apply a blister to the nape of the neck, on account of a return of delirium, when the external inflammation was much diminished. From this time all the symptoms were moderated, and I was able to venture on the use of the lightest tonics."

Erysipelas of the Head in a case of Chronic Rheumatism.

"John Hurst, aged about 38, was admitted under my care on the 19th December,

1829, with rheumatism, which, after passing from joint to joint for some time, assumed a chronic character; but he was receiving essential benefit from small doses of blue pill and the syrup of sarsaparilla, so that he was able to walk without assistance, when, on the 7th of March, he began to complain of a febrile attack, attended with considerable headache and some confusion, and a slight erysipelatous appearance on the face.

Applicentur Cucurb. cruentæ Nuchæ, et detrahatur sanguis ad ʒviij.

Pilul. Colocynth. cum Calomel. gr. xv. statim.

Julep. Ammon. Acetat. cum Vin. Ipec.

March 10th.—The disease has been going on extending over the face, but in a mild form.

Habeat Haust. Sennæ. Repetantur medicamenta.

12th.—Little essential alteration.

Mist. Magnesiæ ad alvi solutionem.

14th.—He was delirious during the night; face greatly swollen and red.

Applicentur Empl. Lyttæ ampl. inter scapulas.

Habeat Hydr. cum Cret. gr. v. statim, et Ol. Ricini, ʒss. post horas quatuor.

Mistura Salina.

Let punctures be made over the whole inflamed surface with the point of a lancet.

17th.—The punctures were performed three times with great relief; the inflammation of the face is subsiding rapidly, but he still wanders a little in his mind.

Hydr. cum Cret. gr. v. statim. Ol. Ricini, ʒss. post horas quatuor.

21st.—Sumat Infusam Rosæ.

24th.—Walking about; his face perfectly restored, without any abscess or almost a trace of the disease. The rheumatic affection is subsiding rapidly, and bandages are now applied to support his ankles."

These cases will sufficiently illustrate the mode of using those means concerning which Dr. Bright expressly says that he never has seen erysipelas prove fatal, when they were used early and perseveringly; but he protests against being supposed to adduce any remedy as infallible. He represents them, and he is no enthusiast, as checking in a remarkable manner alike the local, general, and cerebral symptoms. Another observation worthy of remark is, that if the punctures be very minute, and not "lengthened into small incisions," he has never known them leave any permanent marks even on the forehead. There is generally some, and occasionally insuperable,

objection on the part of the patient to the operation, simple as it appears.

Inflammation from Purulent Discharges from the Ear, &c.

The last class of cases brought under our notice, as productive of inflammatory mischief within the cranium, are those in which there is purulent discharge from the nose or ear, generally, with disease of the neighbouring bones. Numerous examples of this kind are given, but we must content ourselves with a general analysis of them. They shew clearly that the local circumstances above-mentioned not very rarely produce the most formidable, or even fatal, inflammatory irritation of the encephalon. The ethmoid bone and frontal sinuses are certainly less frequently the seat of this mischief than is the temporal bone: one or two such cases, however, are alluded to.

The complication of discharge from the ear, with subsequent cerebral inflammation, is so frequent, that almost every practitioner must have met with it. For the most part, the discharge is first serous, then purulent, and sometimes is very fetid, even where the bone is not diseased. Occasionally the discharge goes off in a few days, and the patient gets well; in others there are headache, troublesome deep sounds, with deafness and vertigo; and if the case terminates badly, we have delirium, convulsions, and coma. The bones are generally found carious; there is ulceration of the membranes, and destruction of the substance of the brain. The dura matter is often extensively detached, and a large collection of pus is found under the pericranium behind the ear. At the commencement, local depletion and fomentations are of service; but when the disease has fairly implicated the bones, it is little under the control of remedies; nor can it ever be free from danger, existing, as it does, close upon the brain and investing membranes. In some cases, as where the mastoid cells are affected, the trephine might possibly be of use. In the case adduced by Dr. Bright (Case 66), inflammation existed in the sinuses of the brain, there having been discharge from the ear, and there being also extensive disease of the heart and lungs; this case is analogous to some of those in Mr. Arnott's paper, published in the *Medico-Chirurgical Transactions*, in which he so convincingly shews the

connexion between inflammation of the veins and certain secondary consequences.

In our next article we shall proceed to consider inflammation of the brain itself.

MEDICAL GAZETTE.

Saturday, October 15, 1831.

“Licet omnibus, licet etiam mihi, dignitatem *Ar-tis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”—CICERO.

THE ALLEGED DECLINE OF SCIENCE IN ENGLAND.

It cannot be denied but that those who adopted the affirmative side of the question were enabled to make out rather a strong case. They were more successful, however, in proving that science *ought* to be in a declining state, than that it really *was* so. The deficiency of royal and ministerial patronage was clearly exposed; the absence of place, pension, and title, from the list of enjoyments that fell to the lot of British philosophers, was distinctively set forth; and, in short, nothing would seem to have been wanting to a full and forcible conclusion, except the actual conclusion itself, which many unhesitatingly drew; whilst a small number of more judicious reasoners saw that there was an assumption in the case—either in the premises, or in the *res probanda*—amounting almost to a fallacy, yet far from being simple, or easy of detection. Those who were fully conscious of the error were, for the most part, as we have already stated, the very persons who most strongly felt the seal of modesty upon their lips. It only remained, then, for the learned “foreigner,” full of enthusiastic admiration for British genius, and well acquainted with the productions, as well of our school as of those

of the continent, to come forward in the ardour of his generosity, and take up the gauntlet of Mr. Babbage. With what success he has combated in the cause we need not repeat, after what we have said of it in our last number; but we may revert once more to the subject of the contest, just to make a few remarks concerning certain of its medical bearings.

It will not fail to have been observed, that the principal question at issue between the contending parties is, whether theoretical and abstract science is on the decline in England or not; or to particularize more distinctly, whether the mathematical and physical sciences are pursued with as much ardour and activity in this country as on the continent. The Messrs. Babbage, Brewster, Herschel, and South, think not; whilst the learned “foreigner” shews himself right willing and competent to support the opposite opinion. But neither party touches upon the condition of medical science in Great Britain—or barely touches on it. It is quite clear that it was not deemed advisable by the former party to attempt to corroborate the position of the decline of our science by a reference to the state of our medicine; whilst our foreign champion, we must say, lost an excellent opportunity of establishing his view of the case by not adverting to the same felicitous topic.

Let science decline amongst us as it may in other branches (and we shall not now enter into the merits of conflicting opinions on the head), in medicine it does not decline. With such names as we could enumerate—were it not invidious to single out individuals where there are so many of the very first order—in anatomy, physiology, chemistry, practical medicine, and surgery, it would ill behove us to despair of our medical commonwealth, or to rank ourselves second to any other in Europe. A most striking difference, it is true, is observable be-

tween the profession as it exists here and as it exists in France and other countries of the continent, but the balance, in point of practical utility, is with one consent admitted to be in our favour; with much less parade and affectation of profundity, we are perhaps the most of any people disposed to turn our stores of knowledge to account—and no sooner, it is observed, have we caught hold of even the simplest elementary principles, than we turn our attention to what may be the best practical application of them. This is the remark of the author of the pamphlet before us, in speaking of the comparative progress of the French and English when proceeding with the cultivation of pure science—but it is equally applicable to the same parties engaged in the cultivation of medicine. The French, moreover, may have more “pride, pomp, and circumstance,” in the externals of the profession; for instance, in the arrangements of their *Ecole de Médecine* and *Académie de Médecine* (both of them subject in every thing to the higher powers of the Minister)—in the co-operation of greater numbers in the compiling of their *Dictionnaires* and *Annales*—and generally in the mode of conducting all their scientific proceedings; yet our own countrymen, singularly enough, without those aids and appliances, have been so fortunate as to secure the palm of all Europe in the matter of unequivocal usefulness, which, after all, is the sum and essence of all that scientific men can pretend to aim at attaining.

One opinion of the author before us, when he attempts to account for the want of diffusion in England of those theoretical views which engage so much of the attention of our foreign brethren, we are not sufficiently prepared to adopt. The English, he says, are not well provided with the knowledge of foreign languages. Neither are the French; and whatever fault may be

found with us for our limited acquaintance with those “whole branches of continental discoveries,” of which Mr. Herschel speaks, it is some consolation that the same is equally applicable to our more theoretical neighbours. But our author is inclined to be more favourable to the pretensions of the German *savans* in this respect: he may be right—though we are not satisfied that he has stated sufficient grounds for such an opinion. What he says, however, of our deficiencies with regard to foreign literature, may be worth extracting. “Since the Latin has ceased, very happily in many respects, to be the common medium of intercourse of the learned in every country, the scientific intercourse between different nations has become cramped by the necessity of learning many foreign languages—at least three or four are indispensably necessary. In this respect the natives of England labour under great difficulties. The difference of pronunciation of the English language from all those spoken on the Continent, renders the task of learning a foreign tongue particularly troublesome to an Englishman; nor does he generally find, in the public schools and academies of his own country, many opportunities of receiving, in this respect, regular and solid instruction. The consequence is, that few Englishmen learn enough of a foreign language to enable them to converse freely with the natives, and to read, without great exertion, the writings of continental authors. There are countries of Europe where no young man could think of studying medicine, mathematics, or natural science, with the help of Latin only, and without being prepared, before entering the university, with a sufficient knowledge of German, English, and French. Many, indeed, are masters enough of Italian to read with ease and pleasure any scientific book in that language, whilst I have known others attain

a tolerable degree of proficiency in the Danish, Swedish, or Spanish; but in England, the number of those who acquire a smattering of French is very small, and still smaller is the number of those who know enough of German to read a book in that language without considerable trouble." Here, we suspect, our foreign friend rather underestimates the attainments of English students.

But, however this may be, we believe much of the complaint might be removed by a more unrestricted trade in foreign books: the market, in this respect, requires a thorough opening: the penalty of being obliged to pay five and twenty per cent. at the very least, to an English dealer for French books, and we believe much more to those who deal in Italian and German, cannot but constitute a serious restriction to the more general diffusion of foreign literature. Among the taxes on knowledge, so much complained of, we know not one which can compare with this for its real practical disadvantages and severity; and whenever we shall have the ear of the Chancellor of the Exchequer, we will use our earliest and best influence in that quarter for abolishing all taxes on the importation of books in foreign languages.

There is much plausibility, though perhaps something, too, that is objectionable, in that part of our foreigner's remarks where he treats of the futility of rewarding scientific men with badges of an order of merit. "In almost every country," says he, "where such distinctions exist, one-half of the ribbons are given to jobbing and patronage; and, upon the whole, we believe that the institution itself has an injurious tendency. Such crosses and badges are but too often the price for which honour and conscience are bought. These gaudy baubles are the hooks and baits by which a prey may be allured, which

could not be taken in any other way. The distribution of these distinctions must of needs belong to government: how are its members to judge of the different degrees of scientific merit? Mr. Babbage scarcely allows to government the capacity of choosing its own scientific advisers—how will it be able to discern those who deserve the 'order of merit?'" Our author must surely admit that there is a difference between choosing a scientific adviser and a suitable person on whom to bestow an order. Nor can we agree with him in supposing any difficulty to exist, granting that "the government" knows any thing about what is passing in the world around them, in fixing on the proper objects for their distinctions. At all events, considering the fewness of honours that await the members of our profession, we believe it must be admitted that the author's opinions, if applied to them, will appear to be somewhat fastidious.

An "order of merit" we should be inclined to consider as a very cheap and simple, and not an unsatisfactory mode of rewarding, or at least cheering the toils of those for whom so few good things are in reversion. They have been, however, long inured to contentment in this respect, and should there be no disposition in the government to comply with Mr. Babbage's suggestions, there will be the less damage done—they will not sink, we are sure, under the disappointment. As to the objection that the patronage of the bestowal of these honours would be liable to abuse—why, so is every other desirable thing. A baronetcy, a knighthood—nay, a peerage, may be frequently conferred on the unworthy; but is this a reason why they never should be bestowed upon men of science as a suitable mark of royal respect? Let but those who palpably merit distinction be even raised above the level of the crowd;

and it will at least secure to them the respect of the vulgar, if there be any thing in that worth having ; and the intelligent may not find it the more difficult afterwards to adjudicate them to their proper places among the learned.

COUNTY INFIRMARIES IN IRELAND.

ONE fact is worth a dozen arguments. We might be preaching for half a year against the propriety of maintaining a particular system ; yet the existence of an “exquisite reason” for its support, in the shape of a profitable monopoly, were stronger than all that we could urge. What is the use of arguing abstractedly on the grossly unfair and unprincipled system of insisting on apprenticeships in the education of the surgical profession in Ireland, so long as the monopoly of the valuable county infirmaries in this country subsists ? The *lucri odor* is an argument too powerful for any rhetoric ; and in this case it is likely to continue so till all question about the matter is set at rest. But all is not quite lost that is in danger. There is still hope of the evil being remedied by a *not-too-late* interference ; and after what we are about to say, it will rest entirely with the parties most interested to take the proper steps for asserting the cause of justice and their rights.

So all-absorbing has been the interest excited throughout the country by the recent proceedings of parliament on *one* question, that the public have been altogether lulled to the progress of certain minor measures, which at any other time would scarcely fail to create a sensation. Among these, we are informed, was a bill for the regulation of the county infirmaries in Ireland, to which a clause had been added for the throwing them open unrestrictedly for the competition of all regularly-edu-

cated surgeons of the united kingdom ; but this clause, it is provoking to add, was thrown overboard, for the gratification and by the intriguing of certain persons attached to the obnoxious system of monopoly. The bill, as it stands, would restrict the enjoyment of those fair objects of competition (that should be), to individuals who have served a five-years’ apprenticeship to members of the Irish College of Surgeons ; and this at a time when that very college has in its possession a recently-bestowed charter legitimating and professedly equalizing the rights of persons educated on the truly liberal system, which makes it unnecessary to enter into bond servitude for the purpose.

We hope this bill has not yet passed into a law ; but if it has, we trust the matter will be properly looked to in another legislative provision still before parliament, and which has reference to the subject in question—the Grand Juries (Ireland) bill, in which a similar fair and conservative clause is inserted ; but to what purpose, if measures be not taken to prevent the recurrence of similar intriguing ? We call upon the surgeons of England and Scotland, as well as the liberally-educated part of the profession in Ireland, to bestir themselves in this matter, and not to suffer a gross and egregious bargain to be struck before their eyes, without entering their indignant protest against it, and at the same time putting forth the assertion of their just claims and equal rights. A short breathing-time has occurred in the progress of parliamentary proceedings : the suspension is not inopportune, nor can be better employed than in investigating the secret plot, by which, if not timely exposed and properly prevented, the profession at large will find itself, when too late, curtailed of a serious share of its fair proportions. We shall take care to return to this subject.

KING'S COLLEGE.

THE opening of King's College took place last Saturday, on which occasion a very luminous discourse on the advantages of science was pronounced by the Bishop of London. This was followed by a very long and not particularly interesting essay on the same subject by the Principal. The Medical Classes commenced on Monday, Mr. Mayo delivering the first lecture.

In our humble opinion the proprietors would have acted more prudently not to have begun at all this season, unless they had been able to do so at the same time as the other schools: as it is, the building is unfinished, and the voice of the lecturer occasionally drowned by the hammer of the carpenter.

REPORTS OF CASES OCCURRING
AT PUBLIC INSTITUTIONS.

WESTMINSTER HOSPITAL.

Femoral Aneurism opened by mistake.

WILLIAM OAKLEY, ætat. 27, admitted Sept. 10th, 1831, under Mr. Guthrie, with a pulsating tumor, nearly circular, about six inches in diameter, and raised about three inches above the level of the surrounding integuments; the apex is about three inches below the middle of Poupart's ligament, on the left side. The pulsation is evident both to the eye and hand; and the sound is heard by the stethoscope very plainly over the whole surface of the tumor, and for about two inches above, and one inch and a half below, in the line of the artery. This is not heard on compressing the artery above. From the account given by the surgeon attending previous to admission, there is an opening at the apex, which is at present concealed by strapping, and from which about one drachm of blood has oozed since admission. On the other side is a blister, of about one inch in diameter, containing bloody serum. The limb is of the natural temperature, and highly œdematous; the artery cannot be felt either in the ham or at the ankle. Face much blanched, but calm; tongue covered with a coat of white, tinged with brown, and

moist; no thirst; bowels open freely; urine scanty, passed with difficulty; this has only existed two days; skin hot, but moist; pulse 110, but feeble; heart beats loudly, without impulse; respiration 30, natural in sound; percussion sonorous; emaciation considerable. He is a book-binder, which occasions constant standing, but has been out of employment for nearly one year: has led a tolerably temperate life, and has never suffered from any disease since infancy. The account he gives is, that between two and three months ago he first observed a beating in the groin, particularly on any exertion. This has increased ever since, and about six weeks ago he first perceived a slight tumor, which at first was not at all painful, but latterly became very much so. He has been attending at a dispensary about six weeks, and at first thought he obtained relief; but the tumor afterwards increased in size. Six days ago an opening was made into it with a lancet, through which a small quantity of coagulated blood escaped; after this a poultice was applied; nothing further happened till the 8th, when a sudden rush of blood took place, and, according to the statement of the man, he lost more than four pints. The surgeon was immediately sent for, who compressed the tumor by the aid of strapping, bandages, &c. and no further hæmorrhage has taken place. By the advice of a second surgeon, who was called in, he was brought to the hospital.

Mr. Guthrie was immediately sent for, and on his arrival, determined to defer the operation to the following morning at ten o'clock, directing the patient to be closely watched, and a cold lotion to be kept constantly applied.

Rx Sul. Opii Sedativ. ℥. xxx.

Aque fontan. f3 x.

℥ft. Haust. hora somni sumend.

Sept. 11th, seven A.M.—Has passed a good night; the tumor is as yesterday; pulse 104, rather fuller; countenance quite calm, still much blanched; skin hot and rather dry; no thirst.

Ten A.M.—Pulse 120, soft; countenance tolerably tranquil; temperature of the left ham $97\frac{1}{2}$ of Fahrenheit, of the right 101.

Operation.—He was placed on the table, the legs semi-flexed, and separated; the body being supported by the surgery-man. Mr. Guthrie then commenced the operation by making an incision through the integuments of three inches in length, beginning a little above and to the outer side of the internal abdominal ring, and carrying it perpendicularly downwards to Poupart's ligament. He then divided the tendon of the external oblique, and afterwards the internal oblique and the transversalis; raising the two latter muscles on the director, the fingers were

then carried down to the artery, pushing the peritoneum upwards: the vessel was now found pulsating, but confined by very dense cellular membrane, which strongly resisted the nail. The depth was fully three inches and a half; this rendered a slight enlargement of the external incision necessary, which was practised towards the outer side. After separating the artery, the common aneurismal needle was carried round, though not without considerable resistance, and the artery finally tied; the greater part of the time spent in this operation being occupied in scratching through the cellular membrane. A single ligature was put in at the external wound, and the man put to bed in pretty good spirits.

He gradually sunk, and died on the evening of the 13th.

Autopsy, eighteen hours after death.—The body presented an appearance of great general emaciation; features considerably shrunk; the limb presented the mottled appearance as far up as the lower part of the aneurismal tumor; phlyctenæ scattered here and there on the inside of the leg and foot; the abdomen felt very tense, owing to a tympanitic state of the intestines. The aneurism contained eighteen ounces of coagulated, grumous blood, besides the coagula adhering to the sac, which extended upwards under Poupart's ligament, in a line with the inside of the ilium. The artery was ruptured exactly where the profunda was given off. The iliac was sound, where the ligature was applied, and the internal coat was fairly divided, with slight redness on each side. The lower end of the artery was filled with coagulated blood, but Mr. G. thought that was from the extension of the mortification. About four ounces of serous fluid, mixed with flocculi of lymph, were found in the abdomen; slight inflammation of the peritoneum, extending about four inches round the incision; the intestines were glued together by lymph; there were old adhesions between the pleuræ, but the lungs were healthy; the heart, aorta, and common iliacs, were healthy.

Abstract of a Clinical Lecture on the above case, by Mr. Guthrie.

The case to which I am desirous of drawing your attention has terminated fatally, as I expected. It was that of a young man, Thomas Cabley, twenty-seven years of age, by trade a book-binder: it appears that he had some sort of swelling at the upper part of the thigh, seven years back, for which he applied to a practitioner for advice; but as it gave him little trouble, he did not

attend to it until within the last three months, when it enlarged, became painful and pulsating, and the limb proportionally weak. The surgeon he applied to poulticed it for three weeks, and, on Monday the 5th, he opened it with a lancet; but, as only blood followed, the opening was closed by compress and bandage. On Thursday the 8th, it burst out bleeding, and the man says he lost four pints of blood. This is probably an exaggeration; but, from his pale and depressed appearance, it is likely that he lost a considerable quantity. On Saturday evening he was sent to the hospital, and on Sunday morning I proceeded to place a ligature on the external iliac artery. Mortification of the extremity followed, and he died on Tuesday night, at eight o'clock.

This is the second case I have had of femoral aneurism sent into the hospital, after it had been opened. I do not believe that in either case it occurred through ignorance, but from inattention; from the practitioner having made up his mind that they were abscesses, and then proceeding in their treatment as such without further consideration.

These cases will shew you the necessity that exists for a patient investigation of disease, wherever it may take place, and more particularly when situated among parts of importance. It would have been impossible to mistake this last case, if the slightest examination had been made to ascertain whether it was or was not an aneurism; for the pulsation was distinct, and the peculiar whizzing noise was clearly perceptible to the ear. In the first case, the aneurism was in the situation of the artery, just as it passes through the tendon of the triceps; and, as the man was old, I preferred doing one operation only, and amputate the limb, but he did not recover. In the present case, the tumor extended up to and beneath Poupart's ligament, near the ilium. It was as large as an infant's head, and was found to contain, after death, eighteen ounces of coagulated and grumous blood, besides about eight ounces of adherent coagula. The artery had given way exactly opposite to the organ of the profunda. Amputation could only have been done at the hip joint, and I preferred the operation of tying the external iliac artery, which I found a difficult undertaking; so much so, that one of

the students, who has seen me do the operation several times on the dead body at lecture, expressed his great surprise at the different appearance the parts assumed. The limb could not be bent in the slightest degree, without giving the man intolerable pain, and the tumor pushed up Poupart's ligament like a bank, so that the artery, after the external incisions were made, was at a considerable depth, and perfectly tense. Bending the body only brought down the peritoneum, with its contents, so as to completely obscure the aneurismal needle, which was, however, passed under the artery, but with much greater difficulty than is usually experienced. This difficulty occurred from the fascia covering it being very strong, and from the vessel lying upon the stretch. It was secured with a single ligature, when the pulsation in the tumor ceased. The temperature of the limb before the operation was $97\frac{1}{2}^{\circ}$ in the ham, and in the opposite, or right ham, 101° . The operation was done at ten in the morning; at three o'clock p.m. the temperature of the left foot was $86\frac{1}{2}^{\circ}$; at seven in the evening it was 96° ; that of the other foot, 102° . The patient complained of pain in the thigh, and in the calf of the leg and heel, which I considered very unfavourable, and expressed my fear that mortification was about to take place. The pulse was 120; the temperature was maintained by the aid of bottles filled with hot water, and by flannel, and an opiate was administered. The next morning the mottled appearance of the leg was decisive of gangrene having supervened; and on the subsequent evening he died, the gangrene having extended up to the tumor. The external iliac, where the ligature was applied, was sound; the aorta was unaffected.

I have elsewhere given it as my opinion, that the operation on an old aneurism is more likely to be successful than on a recent one, of two or three weeks formation; but a small aneurism is always more favourable for the operation than a large one; and here it was too large—it pressed on the collateral branches; it pushed aside and pressed on the great vein, diminishing, I believe, in consequence, the temperature of the limb before the operation, and being the principal cause of the mortification which ensued. If the circulation

through the limb had been preserved, the patient had still many dangers to encounter, all depending on the opening which had been made into the sac. The first would arise from the reflux blood finding its way into the sac, and flowing through the wound: now this would not be, in all probability, of an arterial colour, it would be black, a fact of great importance, and which should never be forgotten, as it bears, in an especial manner, on wounded arteries, in which it is always so. I have seen the artery tied higher up when such an occurrence took place, but it did not, of course, succeed; and subsequently the lower end of the divided vessel, which was discharging black blood, had to be sought for and secured.

In aneurism this is not always the case, but it is frequently so. We had an instance to the contrary in this hospital some time ago, and I will take an opportunity of shewing you the preparation. A man came in with an aneurism in the leg, which had burst and distended the limb in every direction. It was thought advisable by his surgeon to make an incision into the swelling, to ascertain its nature; coagulated blood rolled out, and presently arterial blood in a full jet. This I could prevent by compression; but not a steady flow of it, without any impetus, which came from the lower end of the artery; and amputation was resorted to, but it was not successful. In this case the collateral branches were large, and the communication nearly direct, the artery having burst in the upper part of the calf. If the coagulation in the blood in the sac should have prevented this accident, still from the state of the parts, suppuration must have taken place: it had, indeed, actually commenced on the outside of the fascia forming the sac, and the whole contents would have been gradually discharged. An operation in the lower extremity of the artery would have become necessary, if the inflammation had not extended to it, so as to fill it with coagulum; and, lastly, the drain from this great hole would, in all probability, have destroyed the patient, in his reduced state. All these evils would have been caused by the error of making a small opening into the sac, and shews you the importance of a careful diagnosis.

A patient does not always, however,

die under these circumstances. A man was brought into this hospital some five years ago, with a large, deep, sloughing hole on the anterior and upper part of the thigh, precisely in the situation of this aneurism. From the history of the case, I had no doubt of its having been an aneurism, which had sloughed, and was undergoing a spontaneous cure. It was not, however, effected, for the capsular ligament of the hip-joint ulcerated, and he died from disease of the joint. On dissection, the artery was found to be deficient for several inches.

Mr. Lynn has mentioned to me, that, many years ago, a man was brought into the hospital, with an aneurism in each thigh, which burst at once, and so much blood was lost that he was left in an apparently dying state. The hæmorrhage did not return; the man gradually recovered, and a spontaneous cure of the aneurism followed.

Independent of the history of the case, and many collateral circumstances, there are two great distinguishing marks of an aneurism, the pulsation and the sound. An aneurism always gives a feeling of pulsation, unless it be filled by coagulum and be impervious to the passage of blood through it, which are rare occurrences; or when it bursts, and a quantity of blood is extravasated between the muscles, in the cellular structure of the limb, and under the fascia. In this latter case, the sound of the blood passing through the ruptured vessel may be heard, and it is peculiar.

I drew your attention several times last spring to a remarkable case among yourselves. One student thought it right to bleed another, and taking it for granted that an elastic vessel, which he felt under the skin after he had applied a bandage, was a vein, he opened it, and, on loosing the bandage, abstracted the desired quantity of arterial blood: this alarmed him, and, on becoming aware of his error, he placed a solid compress on the part, and brought his friend, two days after, to me. It was the ulnar artery, running superficially, that he had opened: the external wound was closed, and a small aneurism, the size of the tip of the little finger, had formed. On applying the ear to this, the sound emitted was similar, and just as great, as that which would fall on the ear from a bellows in a smith's forge: and I judged of the

progress towards cure through the obliteration of the artery at that part, by the gradual diminution of the sound. The application of the ear to a swelling in the situation of an aneurism is indispensable; and it will be found, I do not hesitate to say, decisive in most instances of even a very doubtful nature.

Mr. Guthrie then called in a woman labouring under aneurism of the arch of the aorta, and directed the attention of the students to the extent of pulsation under both clavicles, and the single sound, like the stroke of a hammer, which it communicated to the ear, when compared to the double sound of the heart. This woman, he said, came to the hospital about five years ago, with a small aneurism presenting at the right sterno-clavicular articulation; it was called a subclavian aneurism, and the operations on the carotid and subclavian were recommended for its cure. Mr. Guthrie believed he had been blamed for not operating, but he was even then satisfied that the disease was of the aorta. This woman has since had a child, and may yet live to have more; and, upon the whole, Mr. Guthrie believed forbearance to have been the safest and most judicious course of proceeding*.

* The case is taken from the Medical and Surgical, Mr. Guthrie's remarks upon it from the Medical and Physical Journal; from which were also taken Larrey's mode of treating fractures, and the comparison between bleeding as practised in France and England, in our last number.

BOOKS RECEIVED FOR REVIEW.

Observations on Cholera, as it appeared at Port-Glasgow, during the months of July and August, 1831. Illustrated by numerous Cases. By John Marshall, M.D.

LECTURES
ON
THE THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

LECTURE III.—Oct. 7, 1831.

General Observations—Explanation of Terms.

I MENTIONED, gentlemen, in the last lecture, that the occurrence of death—even of premature death, and the occurrence of disease, whether leading to death or terminating favourably, were nothing more than circumstances in perfect unison with the operations of nature throughout the animal and vegetable kingdom; and, indeed, throughout inanimate nature also.

I stated that there was not only a definite period for every animal and vegetable to exist, but that the greater part were cut off before that period arrived; and not only so, but that those which were not cut off suffered more or less derangement from time to time during their existence;—that we were so dependent upon all the circumstances around us for our existence, and that these circumstances were so liable to change, to be in a state of deficiency or depravation, that it was scarcely possible to escape disease.

I mentioned that disease, perhaps, might be defined to be an aberration of function, or structure, or size, in any one or more organs, or an aberration in quality or quantity of any of the fluids, from the sound state; but that it was necessary that a certain degree of these unhealthy circumstances should exist for us to say that a person was labouring under disease; and therefore there is generally added to such a definition as I have just given, “rendering assistance desirable or necessary.” I mentioned this as a defini-

tion of disease in general; and I stated that with respect to particular diseases we usually defined them, not from their ultimate nature, but merely from their appearance—from the symptoms—that is, from every thing that was observed in an unnatural condition in a sick person: the most evident, the most constant, and the chief of these are grouped together, and said to constitute a disease. We do not generally look at the nature of the affection, but merely at the concatenation of the most important, and as far as we can judge, indispensable symptoms. Yet, if the proximate cause is evident, we may put it into the definition, or name the disease from it. For instance, certain symptoms arise so clearly from inflammation of the bowels that we do not hesitate to name the disease inflammation of the bowels, or enteritis. But we seldom know the proximate cause, and thus are content with calling certain convulsions, the falling sickness, and a certain change of colour, jaundice or yellowness.

With respect to the cause of all these symptoms, that, I mentioned, is called the proximate cause, which, when present, makes the disease, which, when changed, causes a change in the disease, and the removal of which causes a removal of the disease. According to the words of writers, *præsens morbum facit, mutata mutat, sublata tollit*. I stated, that besides this cause of the disease, which is called the proximate, those causes which produce this indispensable state, whatever it may be, and which gives rise to the symptoms, are styled remote causes; and I mentioned that these are divided into two—the predisposing, those which give a liability to disease; and the exciting, those which immediately produce it.

I mentioned a few varieties in regard to diseases; that sometimes they affect merely function, sometimes they affect structure, sometimes they affect the solids, sometimes the fluids, sometimes both, sometimes they are general, sometimes local; that they are sometimes acute, at others chronic; that they

may be continued, remittent, or intermittent; that they differ likewise in their fundamental nature; that they, of course, differ according to the cause which produces them, according to the texture which they affect, and likewise according to the organ to which that texture belongs.

I must now enter a little more minutely into the explanation of certain expressions which will be used throughout the course, because, unless they are understood, it will be impossible for me to speak intelligibly. The whole doctrine of disease together is called *general pathology*. Pathology is the science of disease—the *agroti hominis scientia*—while physiology is the science of man in health. I of course mean human physiology. With regard to pathology, I stated in the last lecture that sometimes an attempt has been made to limit the term to signify diseased structure, but certainly pathology implies the symptoms of a disease, and every thing relating to disease, as well as the particular circumstance of change of structure.

General pathology is commonly said to embrace four particulars: First, *general nosology*—that is to say, an account of diseases in general, and an account of their chief differences. Secondly, an account of the symptoms of disease, which is called *semiology*, or *symptomatology*. Thirdly, the causes of disease, which is called *etiology*. And, fourthly, the treatment of disease, which is called *therapeia*.

With respect, however, to pathology, there is not only a general but a special pathology, which respects particular diseases; and if the epithet *methodical* is attached to *nosology*, an arrangement of diseases is meant—a classification of the various affections to which we are liable. I shall first speak of what is called *general nosology*, or the consideration of diseases in general. These may be local or general: when they are local, however, they seldom continue so without producing more or less general effects. I stated in the last lecture that some contend that all diseases are local—that they are seated in some particular spot or organ; but I mentioned my dissent from that doctrine, because in scurvy, for example, all the blood seems vitiated, and all the solids, without our being able to fix upon any particular spot. Diseases vary in their symptoms, and vary in their course, according to the texture which they affect. You know that the body consists of a certain number of textures—that the various parts of the frame may be resolved into a certain number of particular tissues, or textures, as they are called. Now some diseases affect certain textures, and others affect other textures; and the symptoms of diseases, and their course, are influenced very much by the texture which is thus affected. To take inflammation, for example, we shall find that

the symptoms are very different when it affects a serous membrane, from what they are when it affects a mucous membrane. Again, the symptoms are very different when it affects the skin, or when it affects a bone. The symptoms of disease, too, and the course of diseases, vary exceedingly according to the organ. Diseases may not only attack a particular organ, but they may attack a particular texture in a particular organ, or they may attack all the textures of an organ. Now when they do attack any particular organ, the importance of that organ to the economy, the function which it performs in health, the whole set of relations of that organ, greatly influence the symptoms. For example, inflammation which may be of no consequence in the finger, may, though only to the same extent, be fatal when seated in the stomach; a little ulceration of not the slightest importance on the hand may produce death if it occur in the stomach; an affection in the brain, or in the heart, may be productive of very different results—a very different degree of danger from what it would be if seated in many other parts.

Diseases likewise vary exceedingly, accordingly as they are attended by excessive or diminished action. Some diseases are characterized by an inordinate violent action of the part; the natural state of the part seems augmented. Whatever is done in health is done ten times more in the disease, at least for a time, till the strength is exhausted, or the state gradually subsides into health. Other diseases are characterized from the beginning, or nearly so, by a great diminution of action; the natural functions of the part decline exceedingly, so that the depression is the character of the disease. If the part affected be one characterized by feeling, as the surface of the body, the feeling may become very intense; if it be one whose function is motion, motion may become very intense, and you may have convulsions as the consequence. On the other hand, you may have a diminution of feeling, perfect torpor, insensibility; and such an absence of all power of motion that the part is useless to the individual. Again, if the part be one which secretes, the secretion may be in excess; and if it cannot escape we have dropsy. The secretion, on the other hand, may be exceedingly diminished, so that in the case of the kidneys no urine can be formed, and in the case of the skin the surface shall be perfectly dry.

Some diseases, among structural affections, are attended by a great dilatation of the part—the part becomes much dilated, beyond its natural extent;—on the other hand, in some diseases, the parts become contracted and diminished. In some diseases the parts become exceedingly hardened, and, from being naturally soft, they become

as firm as cartilage, and are sometimes converted into absolute bone. Again, very firm parts will occasionally become perfectly soft, and bone will become as pliable as muscle. I myself have seen the liver, to all appearance, become softened down to a pulp in the course of three days.

Again, diseased parts will become exceedingly full, distended with fluid; and this may be general or local—it may be local congestion or universal plethora of the body. In other instances, the parts become devoid of fluid and shrink, and this is observed also generally or locally. Alterations of texture likewise take place, and alterations in the quality of the fluids. The texture—to say nothing of induration, softening, hypertrophy, or atrophy—the texture of the parts sometimes becomes perfectly different from what it is observed in the state of health. So with respect to the fluids, they will frequently be formed of a character totally dissimilar from what they should be. The urine is sometimes any thing but genuine urine, and the bile is sometimes so pale that you can scarcely recognize it as bile; and so with respect to the blood itself—it is sometimes very little more than a reddish watery fluid.

These are important and essential differences in disease; there are, however, many other varieties, which are considered more or less accidental—that is to say, which do not affect the nature and course of the disease. For example, some diseases are hereditary, and this will not at all influence the nature of their course or duration; but some diseases may be hereditary in the particular individual, and other diseases are not hereditary, not transmitted from parent or ancestor to offspring or posterity, but still are born in the individual—seem to be implanted in him at his first formation; and then they are called only *connate* or *congenital*. A disease which is connate, or congenital, may be hereditary; but it is not necessarily so. All diseases which are not hereditary, nor connate or congenital, are said to be *acquired*.

Then diseases—to speak still of accidental varieties—are sometimes primary and sometimes secondary. Sometimes the disease which occurs is the first; but sometimes after one disease has taken place it is joined by another—that is to say, exists with another, or gives such a predisposition that another is produced; but it is of no consequence to the nature of a disease, whether it is primary or secondary.

Again, diseases are sometimes said to be *sporadic*, sometimes *endemic*, sometimes *epidemic*. A disease is said to be sporadic when it occurs from an accidental circumstance occurring to any particular individual—when it is a solitary accidental case. Hence, when a person, by exposure to cold, suffers inflammation of the lungs or intestines, he is

said to labour under a sporadic disease. These are insulated cases, having no connexion with each other, not having any general prevailing cause. But if diseases occur from some general and temporary cause affecting a whole population, then they are said to be epidemic. Sporadic and epidemic, therefore, stand contrasted with each other; the former class of diseases being those which occur occasionally and accidentally, from some peculiar circumstance happening to the individual; epidemic are those which affect a large mass of persons from some general prevailing cause. Again, diseases are sometimes said to be endemic—that is to say, when they do not arise from any general influence at a particular time, pervading a population, but when they spring from certain causes fixed and inherent to a certain place—when certain places in which people reside send forth causes of disease which all persons who come to that spot are liable to, but which persons do not suffer unless they go there. This is the distinction between endemic and epidemic diseases—the former being confined to the inhabitants of a particular spot, and the latter being those which arise from a general cause, taking place only from time to time, and pervading, not a particular spot, but a considerable population.

Another difference in diseases, not at all affecting their nature, their course, or their treatment, is, that they may arise from a common cause or from a specific contagion. Some diseases are contagious and some are not, but the symptoms do not vary in their essential nature; so that we are continually very much in doubt as to whether a certain disease is contagious or not. There is nothing in the disease itself to make us say that it must necessarily be contagious, and the greatest disputes are carried on as to whether a particular affection is or is not contagious.

Diseases have likewise been distinguished according to the time of year at which they occur, so that we have vernal, summer, autumnal, and winter affections—*vernales*, *æstivi*, *autumnales*, *hyemales*. Other accidental differences of disease arise from their seat, whether they are internal or external—and then, again, as to whether they are fixed, or whether they wander. If they cease in one particular part, and appear in another, they are said to be *metastatic*, or *retrograde*, or *retrocedent*—if disease suddenly cease in one part, and another become affected, a metastasis, or change of place, is said to have occurred.

Then diseases differ according to their severity. Some are exceedingly severe, others are light—some are said to be mild, and others are said to be malignant. Those which are said to be of a malignant character, however mild they may be in appear-

nance, are sure to baffle all the resources of our art, unless we can eradicate the affected part by surgical operation, which sometimes is, but sometimes is not, possible. However, the word malignant is sometimes employed simply to denote a certain degree of severity; it is a term of rather indefinite meaning. Small-pox is said sometimes to be mild, and sometimes malignant;—and, again, a sore which is of a cancerous nature, however trifling the pain it may be attended with at first, but which is sure to go on to ulceration, violent pain, and, at last, destruction of the part, is also said to be malignant.

Diseases vary likewise as to their duration. If they be exceedingly short, so as to terminate within four days, they are called by Latin authors *acutissimi*; but if they terminate within seven days, then they are called *peracuti*. We have no English words to signify the difference between these two durations. If they terminate within 14 days, they are called *acute*; if they run on to 20 days, then you will find authors calling them *sub acute*; and some are so nice in their terms, that if they last forty days they call them *acuti decidui*; and all that run on above that period are called *chronic*. It is sufficient, perhaps, to remember, that an acute disease is considered one which terminates within 14 days—a sub-acute one which terminates within 20; for though some authors make a still more nice distinction, and call a disease sub-acute which terminates within 20 days, and apply the term *decidui acuti* to those which extend to 40 days; yet if the disease extend to or above 40 days, we may consider it chronic, at least I fancy a patient would think we were justified in so denominating it.

Diseases, again, are considered as they are continued, or intermittent, or remittent. Continued diseases are generally understood to embrace two varieties as to course; namely, diseases which pursue one uniform course to the end, and are called *continuent*—and those which relax from time to time, and are called *remittent*. You find many persons speak of continued disease as distinct from remittent, and it is so common that we are justified in using the distinction; but some make a nicer distinction, and use the word continued to include *continuent*, that is to say, one which preserves the same tenor to the end, and *remittent*, one which, although it never ceases, yet relaxes from time to time. Diseases, however, are sometimes *intermittent*; they absolutely cease altogether at intervals, and then recur again. If intermittent diseases recur and disappear at regular intervals, then they are called *periodical*. A periodical disease is necessarily intermittent; but an intermittent disease is not necessarily periodical. Intermittent embraces the circumstances of simple

intermission, no matter when or how; but it embraces also regular intermission—periodical disease. The presence of a disease which is intermittent, is called the *paroxysm* or *exacerbation*, these being considered synonymous terms, and the interval which occurs between them, is called the *intermission*, or, in case of febrile disease, the period of *apyrexia*—the period of the absence of pyrexia.

I fear being troublesome in mentioning the meaning of so many terms, but it is absolutely necessary that they should be understood before we proceed to speak of particular diseases; and I will now make a few more minute observations in regard to what I said of the causes of disease.

The remote causes I mentioned have been divided into two—the predisposing and exciting; those which are exciting, you will find are by some authors called *occasional* or *procatartie*. Generally, in England, we say predisposing or exciting, but in foreign books you will find a variety of other names employed.

In regard to the predisposing causes of disease, they depend upon a very great number of circumstances. Each particular age, for example, is predisposed to particular affections: the child is predisposed to one kind of disease, the youth to another, the adult to another, and the old man to a very different set. Climate, also, causes a great difference in the disposition to disease; the season of the year, likewise, has a great effect; the habit of the individual, as to temperance and sobriety, as to a natural or unnatural and artificial course of life, has a peculiar influence; all these circumstances cause a predisposition to different affections. In regard to some diseases there is not so much a predisposition required as a want of indisposition. For example, almost every one will take the small-pox, the measles, and the hooping-cough; so that we can hardly say that there is a predisposition to these diseases; the cases in which they do not occur are rare exceptions; and we are more justified in saying, when these diseases will not occur in spite of the presence of contagion, that the person is indisposed to them, than that those who catch them are predisposed to them—that is to say, by nature we are all more or less liable to them; and it would be almost an abuse of terms to say that we were predisposed to them; all that appears to be requisite is, that there should be no indisposition to them.

In regard to the exciting causes of disease, they have been generally classed in three orders—those which excite or stimulate, and those which depress or debilitate, and those which exert a physical or physico-chemical action. Heat, and excess in wine, are stimulating causes of disease; the depressing passions, and an excessive loss of blood, may be instanced as

debilitating causes of disease; and these debilitating causes you will find, when you read some Italian authors, spoken of as *contra-stimulating* causes. Many causes, however, cannot be said to depress or stimulate solely; they exert a peculiar action, which is not to be thus explained—it is something we do not understand. For example, malaria, which produces ague, is a certain agent perfectly unknown to us, except so far as regards the situation in which it is produced. Malaria produces a set of symptoms of so peculiar a nature, that we cannot say it is a mere depressive or contra-stimulating agent—that is to say, though the first symptoms of ague produced by it are those of extreme debility, yet if we weaken the body to the same extent in various ways, by bleeding and other means, we do not produce that train of symptoms which are known to us as intermittent fever. Therefore, we have stimulating, depressing, and physical or chemical causes, which are sometimes called *stimulantes*, *contra-stimulantes*, and *irritantes*. We must not, in medicine, be very nice about the etymology of our words—that is to say, we must employ words of a certain meaning, so as to be clearly understood; but we shall find words signifying something very different from what their etymology would lead us to suppose. Nor is this remark confined to physic; it applies equally to anatomy; and the only object should be to become understood among ourselves—to know what ideas are meant to be conveyed when certain expressions are used.

An exciting cause may become a predisposing, and a predisposing an exciting. For instance, malaria excites ague. But a person who has been exposed to malaria may not have ague till he accidentally gets wet through, and then this excites the disease to which the malaria had only predisposed him. Again, if a predisposition continues to increase, disease will happen without any exciting cause. Plethora of the head may increase till a fit of apoplexy occurs, without stooping, overloading the stomach, or any common exciting cause of a fit taking place.

Among the most common causes of disease are aberration with regard to six particular circumstances, which have been very strangely called *non-naturals*. The air we breathe, the food and drink which we take, the retentions and excretions, motion and rest, sleep and watching, and the various passions of the mind, which are all natural enough, are called by old writers *non-naturals*; and others, seeing the strangeness of this expression, have called them *things necessary to life*—that is to say, things which are necessary in order to the continuance of our existence. The great sources of disease are an aberration from that state of all these which conduces to health. For example,

with respect to air; vitiation, I need not say, produces a variety of diseases—fevers, and many others. I need not say how much our health must depend upon the wholesomeness of our food and drink, and upon a proper quantity of them. I need not say that the body cannot bear more than a certain degree of exertion—that many diseases arise from fatigue; and that, on the other hand, excessive rest and indolence produce a collection of fluids in various parts of the body—stagnation, plethora, fatal dropsy, and various organic diseases; so with respect to sleep and rest, alternations are absolutely necessary; and we every day see persons who, for want of sleep, become the victims of fever, and gradually of the most destructive diseases. So with respect to the passions of the mind; there is scarcely a disease, with the exception of those that depend upon contagion, to which they do not give rise; nor is there any one part of the body, in fact, exempted from disease through the passions of the mind. No one can imagine what a vast number of diseases, not only functional but organic, arise simply from unpleasant passions of the mind—that is to say, from grief and deep-rooted sorrow, from violent anger, from regret and chagrin, and all those feelings which are of an unpleasant character. On the other hand it is also to be remembered, that passions of the most agreeable kind, excessive joy, for instance, may have almost as injurious an effect as those which are of an opposite character.

DR. PHILIP'S REPLY

TO

DR. PROUT'S PAPER IN THE LAST
NUMBER OF THE MEDICAL
GAZETTE, ADDRESSED TO THE
EDITOR.

*To the Editor of the London Medical
Gazette.*

Cavendish Square, Oct. 17, 1831.

SIR,

I HAVE already said that I cannot stoop to Dr. Prout's language; to his epithets therefore I make no reply. I shall confine myself to those faults of the style, and substance of his paper, which interfere with the questions between us.

I expected that after so long an interval, his reply would have been in a different tone; but it is the same in its expressions, its inaccuracies, and its shifting grounds without acknowledgment.

As I send with this reply an essay, being an attempt to ascertain how far chemistry is applicable to the explana-

tion of the phenomena of the living animal, and the cure of its diseases, I shall here only make some general observations in support of the foregoing statements, and adduce a few specimens of Dr. Prout's mode of replying, and a few of the facts to which he makes no reply. It is quite evident, that from discussion with an opponent who only shifts his ground on every new exposure of inaccuracy, nothing profitable can arise. The course I am about to pursue will, I hope, place the subject of our dispute in a clear point of view, which the observations of my antagonist serve only to perplex.

His language, indeed, is generally obscure, and sometimes such as makes it impossible to arrive at his meaning. The peculiarities of his style, as every reader must remark, whether he speaks of himself or others, whether in his lectures or his replies, every where, in short, except in his account of his chemical results, where there is no room for them, are the substitution of positive assertion for all proof and even illustration, and promised for present performance. It is remarkable that in his replies he constantly accuses me of a fondness for verbal disputes, while I have been obliged in almost all of mine to complain of his dwelling almost solely on this part of the subject, and not replying to the facts I had adduced, a complaint I am now again obliged to repeat, and shall presently illustrate by instances.

The truth is, that on the one hand the discussion is constantly encumbered by the extreme inaccuracy of Dr. Prout's expressions; and on the other, as he finds it more easy to quibble about words, instances of which I am just about to adduce, than facts, it is very difficult to obtain from him any reply respecting the latter, proofs of which I shall also adduce, for I have throughout the discussion made no unsupported assertions; while on the part of Dr. Prout all the assertions are of this kind, which consequently may be, and in fact almost always are, the mere expressions of an angry man.

I am now to adduce specimens of Dr. Prout's mode of replying. A few, I believe, the reader will think sufficient, and I have no wish unnecessarily to prolong this reply.

In the 40th page, at number 4, he observes, "the next point which I deem

it necessary to notice is Dr. Philip's opinion on the nature of the nervous principle." "Does Dr. Prout (Dr. Prout here quotes my words) then consider the terms nervous and living principle as synonymous? principles that have not one quality in common?" Dr. Prout proceeds, "To which I answer that I *do* consider the nervous principle to be a living principle, and beg to ask who besides Dr. Philip does not?" I might, I believe, with great truth, reply, those who are better acquainted with the subject than Dr. Prout: but of this hereafter. Our present object is Dr. Prout's mode of replying to my question.

I accense Dr. Prout of using the terms nervous and living principle as synonymous. To which he replies, that he *does* consider the nervous principle to be a living principle. It is hardly possible to suppose that he does not see that, whether the nervous principle be a living principle or not, it cannot be synonymous with the living principle usually so called, which pervades every part of the living body; whereas it is notorious that the nervous principle is confined to a certain set of organs. For what purpose, then, does he make this reply? Is it with the hope of persuading the careless reader that he has made a correct reply?

I must beg the reader's patience while I adduce one more instance of the inaccuracy, to say the least of it, of which I complain.

I have repeatedly called Dr. Prout's attention to his new term *merorganization*, and pointed out the inconsistencies attending its composition and employment. He at length gives his reply. It will at once elucidate the nature of this reply, to ask Dr. Prout why he labours in it to confound the terms different *degrees* and different *kinds* of organization,—for, according to his present *corrected version* of what he formerly said, these terms are used indifferently. He says, "Does the organization of the zoophyte not differ, *in kind or degree*, from that of the human being?" And in another part of the same page, "admitting the existence of different *degrees or kinds* of merorganization." In the original definition, we see nothing of difference of kind. The term expresses only difference of degree. He there says, "I have provisionally adopted the term *merorganized* (*μερος, pars*

vel partim), meaning to imply by it that bodies, on passing into this state, become *partly, or to a certain extent, organized*."—Phil. Trans. for 1827, p. 375.

I objected to a word which implies different degrees of organization, and it is changed to different kinds of organization, to which the objection, of course, does not apply. He affects to think *kind* of the same import here as *degree*; for it is difficult to suppose that Dr. Prout really does not perceive that these terms are, as far as applies to our argument, of the most opposite significations, the one exposing him to the whole force of my censure, while the other as perfectly relieves him from it. I accused him of introducing a term to designate different degrees of organization, without being in possession of a single fact to prove that such degrees exist. He attempts to relieve himself from the censure, by pretending that by degree he means kind! That there are different kinds of organization, of course, no one can question. It would be difficult, I believe, in a grave discussion, to find a parallel instance of defence. Besides, Dr. Prout, in his hurry to escape the censure, forgets that this new meaning suits not the composition of his term. He forgets also, that such means could blind no man whose opinion was worth a moment's consideration. It was Dr. Prout's part either fairly to shew on what principle he spoke of different degrees of organization, or to confess his error.

So much for the meaning of his term; his attempt to vindicate his use of it replies to itself. I repeat, that if the animal merorganizes the food, it must, according to his original definition of the term, possess a disorganizing power, because all admit that the food is wholly organized when it enters the stomach; and Dr. Prout *says*, it is there rendered merorganized, and therefore, according to that definition, only "*partly, or to a certain extent, organized*."

* Dr. Prout says I am unacquainted with the refinements of modern chemistry, but, as is his custom, adduces no instance of my ignorance. The degree of my knowledge has nothing to do with the question between us. However great may be the improvement in chemical knowledge, no improvement can change the nature of the science. With regard to Dr. Prout's desultory observations on galvanism, the accompanying essay will show that, however applicable they may be to his chemical experiments, they are wholly inapplicable to the functions of the living

I shall conclude with a few of the instances in which he finds it convenient to make no reply; for it is not so easy to perplex the reader respecting facts as terms.

In the 4th page of my observations on Dr. Prout's Gulstonian lectures, I have stated, that in his summary of digestion he confines himself to the mere chemical part, overlooking all the other equally essential parts of that process. My words are, "although the gastric juice be healthy, and consequently capable of effecting the due chemical changes on the food, the functions of the stomach may, notwithstanding, be wholly deranged, and no proper chyme transmitted to the duodenum. If that portion of the food which has undergone the action of the gastric juice be not duly separated, and kept apart, from that which has not, and in this separated state duly carried forward towards the intestine—if an error in any one of these functions take place, the office of the stomach is just as certainly deranged as if the chemical part of the process had failed; yet, in Dr. Prout's observations on the office of the stomach, the chemical part of it alone is referred to, as if it were in this alone it consisted."

The present is the third reply I have written to Dr. Prout since the publication of the foregoing sentences, but I have been able to obtain no reply from him respecting the facts stated in it, and others which I have pressed on his attention.

I shall trouble the reader with but one other instance of this kind.

In the same page of my observations on Dr. Prout's Gulstonian lectures, the reader will find the following paragraph:—

"Prepared as the reader must now be for Dr. Prout's partiality to his favourite science, he can hardly be prepared for the following prediction in the 9th page of his lectures:—'I will venture to predict, that what the knowledge of anatomy at present is to the surgeon in conducting his operations, so will chemistry be to the physician, in directing him generally what to do, and what to shun.' Does not the surgeon guide his knife solely by a knowledge of anatomy—a knowledge of the parts and their relative position? Will

animal; and independently of this consideration, it is ludicrous to attempt to disprove a simple fact by any train of reasoning. See page 76.

it be asserted that, let our knowledge of chemistry be as perfect as we can suppose it, the physician could regulate his practice on chemical principles alone? Could chemistry give him any knowledge of even the simplest principles of medical treatment? Could it tell him, for example, that a copious discharge from the bowels will relieve the turgid vessels of the brain; or that that by the skin will allay the symptoms of fever? But Dr. Prout may say, it will assist in his choice of the means by which these effects are produced. Undoubtedly it will. Here chemistry is in its proper place; but of what use would the chemical knowledge here be, if the laws peculiar to the animal body had not, in the first instance, supplied the indication of cure?"

To this paragraph Dr. Prout, after having been repeatedly urged to reply to it, replies by the following passage, in the 44th page of the last number of the Medical Gazette—I say to the paragraph, for to the fact there is no reply:—

"Dr. Philip next attacks what I have said on the powers of chemistry, when sufficiently understood and rightly applied, of 'directing the physician generally what to do, and what to shun;' and after stating a variety of objections quite beside the point in question," (what are they!) "ends by observing, 'Dr. Prout may say that chemistry will assist in directing his choice of the means by which these effects are produced. Undoubtedly it will. Here chemistry is in its proper place.' But then (just as if I had laid down the rule, neglect the laws of the animal economy, and attend only to chemistry) he lapses into the old story, and exclaims, of what use would this chemical knowledge have been, if the laws peculiar to the animal economy had not, in the first place, supplied the indication of cure?"

The substance of this pretended reply may be stated in a few words. Dr. Prout's original position is, that what anatomy is to the operating surgeon, chemistry will be to the physician, in directing him generally what to do, and what to shun. When he is told that chemistry can never, in the nature of things, be to the physician what anatomy is to the operating surgeon, because it cannot direct him even in the simplest case of medical treatment; while by anatomy

alone the operating surgeon is directed in all cases without exception; he neither attempts to prove his own position, nor to disprove his antagonist's, but greatly modifies the former, and simply *asserts* that the latter is quite beside the point.

Dr. Prout continues, "I observe in his last letter the doctor recurs again to this point, and places in juxta position the above observation, and one in which I have elsewhere said, that I do not know a single instance in which chemistry can be directly applied to the purposes of the animal economy, as if the two were in opposition to each other. But the fact is quite otherwise. The absurd idea, indeed, never entered into my head, that chemistry at any time will ever be capable of being directly so applied; but that it will be capable of doing all I have anticipated, in an indirect manner, I have not the least doubt." This is one of Dr. Prout's promises; but he does not say, nor can any human being conceive, how it is to be accomplished; and as to reconciling the two passages contrasted in my last reply, and to which he here alludes, this is an attempt he very prudently declines; and thus adds another to the many instances in which I in vain look for a reply.

Dr. Prout still accuses me of not having given his favourite science a place in my Inquiry into the Laws of the Vital Functions. I explained, in a former reply, that it is only in a certain department of physiology that chemistry has any place. Now my Inquiry does not include this department; because, as I have explained in that Treatise, it is an attempt to trace the general laws of the animal economy, not to descend into the particulars of its various processes; and when Dr. Prout says, that if I had availed myself of the aid of chemistry it would have rendered my positions more perfect, of which assertion, as usual, he gives neither proof nor illustration, he only shews himself unacquainted with the nature of the Inquiry; and, indeed, has, in several of the instances which have been adduced, betrayed a very imperfect knowledge of its subject. My object was to obtain and communicate a correct and comprehensive view of the great laws of the animal economy, respecting which there had been, among physiologists, so much discussion and so much contrariety of

opinion—not to trace minutely the steps of any particular class of its phenomena, but to determine the great outline to be filled up by the more partial and minute labours of those who were to follow me. Accordingly, in one of the last papers which the Royal Society did me the honour to publish, I observed, “I am fully sensible of the vast extent of the subject, and that it is only the great outline which I have attempted to trace. If this has been accurately laid down, my object has been accomplished.”—Phil. Trans. for 1829, p. 262.

I cannot conclude this correspondence without saying that I have reason to complain of Dr. Prout, in which, I think, every candid reader will agree with me. If I was in error, why not calmly point out the error? To substitute assertion for proof, and abuse for argument, might hurt his opponent’s feelings, but could not in any other way promote his views.

Dr. Prout again refers to the origin of our discussion. I therefore again say, that it was with great reluctance, and not till after much hesitation, that I entered into it. Having devoted so much time and labour with a view to the improvement of physiology, was it not painful to be publicly told, by a person supposed to be well versed in the subject, that no advance had been made in it for 20 years, as nearly as possible the period of my labours? He says, indeed, this observation did not apply to me, because he includes physiology in metaphysics; but this he did not explain; and it was impossible either for myself or any one else to know it. Besides, I have shewn that, now that he has given his explanation of metaphysics, it will not apply to the expressions used in his lectures. I venture to maintain, that he cannot find one man who will say that he could, from his lectures, infer the explanation he has now given.

As to the note in my first communication, to which he refers, there is no body, except himself, who will not at once see, that what is there said is merely adduced as a proof of his inaccurate use of the term, and can admit of no other explanation. Two things, at all events, must be admitted, that if he did use the term in the new sense he now explains, he should have defined that sense; and it should have corresponded with the expressions used in his

lectures, which I have proved it does not.

As I have reason to hope that this may be the last reply that I shall feel myself called on to make to Dr. Prout, it only remains, sir, that I should thank you for the attention with which you have honoured my communications. I hope the essay which accompanies this letter, and which presents a summary view of the functions of the more perfect living animal, in several respects different from any other with which I am acquainted, will, if it prove to be correct, in some degree compensate for the tediousness of this reply. Nothing but a desire to maintain the truth could have induced me thus long to persevere in such a discussion.

I am, sir,

Your obedient servant,

A. P. W. PHILIP.

A REVIEW

OF

THE FUNCTIONS OF THE LIVING ANIMAL BODY;

Being an attempt to ascertain how far the Science of Chemistry is applicable to the Explanation of its Phenomena, and the Cure of its Diseases.

BY A. P. W. PHILIP, M.D. F.R.S. L. & E.

FROM the following view of the functions of the living animal body, founded on the statements in my first communication to the Medical Gazette, it will not be difficult to see how far chemistry is applicable to explain its phenomena, and assist in the cure of its diseases.

The functions of the living animal body may be divided, according to their objects, into two great classes; those which maintain its existence, and those which connect it with the external world. Corresponding to this division we have seen them divided, according to their nature, into the sensorial, on the one hand, and the nervous and muscular on the other. The sensorial alone are the source of those functions which connect the more perfect animal with the external world. The nervous and muscular alone are the direct means of maintaining its existence.

The difference in the nature of these sets of functions, is essential. There is

a chasm between them which no labour can enable us to fill up; and the attempts which have been made with this view have only convinced us of their futility.

Thus different in their nature and their objects, in their working, if I may use the expression, they are intimately associated. As the life of the animal directly depends on the nervous and muscular functions, as far as we see, the sensorial functions cannot exist independently of them; and we certainly know that, in the living animal, the sensorial can neither operate, nor be operated on, except through the nervous and muscular functions; nor are the nervous and muscular independent of the sensorial functions, because the animal has not the means of existence within itself, and the nervous and muscular powers afford no means, I speak of the more perfect animals, of obtaining the necessary aids from without, except under the direction of the sensorial powers.

As the animal becomes imperfect, and approaches the nature of the vegetable, the sensorial power dwindles; and the lowest animals can extract their nutriment from air and water, which being generally diffused, are at hand, and consequently obtained without any sensible effort on the part of the animal. His life, therefore, although not independent of the external world, is, like that of the vegetable, independent of any act of volition.

As we rise in the scale of animals, the sensorial power becomes more perfect, and in the same proportion more essential to existence. From those animals which obtain food without any act of volition, we come to those who can only obtain it by such an act; but who still, without any act of this kind, obtain the influence of the air, yet more immediately necessary to their existence.

We arrive at length at the most perfect class, which can neither obtain food nor air, except by an act of the sensorium; for in them the sensorial power is as necessary for the inhalation of the air, as the ingestion of the food*. When sensation ceases, the more perfect animal as certainly ceases to breathe as he ceases to eat.

Such appears to be the constitution of our bodies as far as our existence de-

pends on the external world, and therefore on the sensorial power. But with this world the sensorial power connects us in a manner far more extensive and infinitely more varied. It is the source of enjoyment, the end of our being.

Here, as in maintaining life, it is still through the nervous and muscular powers that the sensorium operates. Through the former it receives all its impressions, and transmits all its dictates. But the nervous, like the sensorial organs, are incapable of communicating any impression beyond the limits of the animal body itself. For this purpose the muscular system is necessary.

By its means our powers are rendered active with respect to the external world. As through the nervous system we are influenced by that world, through the muscular system we can influence it. By giving motion to our limbs, it enables us to impress the inanimate objects which surround us, as by giving language to our thoughts, to influence the sensorial powers of other beings like ourselves.

It is thus by the impressions we receive and communicate that the wide field of enjoyment is opened, and not to the individual alone, but through him to other beings, who resemble him, and who repay him in kind. Thus happiness accumulates, and with it knowledge, for the experience of each becomes the experience of all, and the savage is changed into the industrious mechanic, the learned academician, and the contemplative philosopher.

BUT our present object is not the relation which the individual bears to the world which surrounds him, but the powers on which his own existence and well-being depend; and I think it will be found on an inquiry into the nature of these powers, that we have sufficient data to determine how far they are peculiar to the living animal, or partake of the nature of those which operate in the inanimate world, and consequently how far we may indulge in a rational expectation of deriving assistance from other sciences, in tracing the laws of the science most interesting to us, that of our own bodies.

I had occasion, in my first communication, to point out the general nature of the powers of the living animal, and the relation they bear to each other,

* My paper on the Functions of the Nervous System, in the Philosophical Transactions for 1829.

deduced not from the fanciful theories which have filled so many volumes, and added so little to our knowledge, but from an extensive and very laborious set of experiments, whose subjects are not such as bear a certain analogy to the functions of the living animal, but those functions themselves.

From these experiments it appeared, that in the more perfect animal there are three distinct powers, each in their nature independent, though in their organs more or less directly dependent on the others, and more or less capable of being influenced by them.

Two of these powers, the sensorial and muscular, are evidently peculiar to the living animal. No other power bears such an analogy to them as can suggest a doubt on this subject; but the case is different with respect to the nervous power. Its effects bear too striking an analogy to many of the processes of inanimate nature not to suggest the idea, that the power which operates in both may be the same. Hence the best-informed physiologists have long looked to this power as that which probably forms the link which connects, if I may so speak, the animate and inanimate world.

In entering on the inquiry respecting the nature of the nervous power, I endeavoured, in the first place, by the aid of many experiments, to ascertain the line of distinction between the nervous and sensorial functions, that it might clearly appear what belonged to each power; for it is the sensorial power alone with the functions of which those of the nervous power can be confounded, the function of the muscular power being simple and well defined. In order to render the results the more certain, I endeavoured to ascertain this line by two different sets of experiments, conducted on different principles, the object of the one being to ascertain what functions remain after the sensorial power is withdrawn, and of the other, what functions fail on withdrawing the nervous power.

I was thus enabled accurately to ascertain what functions belong to the latter power*, and was, therefore, prepared for ascertaining experimentally, whether there be any power which operates in inanimate nature capable of all its functions; and in galvanism I found such a power.

It passes along the nerves in both directions. It impresses the sensorium; it excites the muscles; it effects the formation of the secreted fluids from the circulating blood; it preserves the structure of the various organs during the performance of their functions; and it causes an evolution of caloric from arterial blood: for these I had found to be the functions of the nervous power*, and as far as I myself and others well versed in such subjects could see, in the experiments referred to, it performed all these functions as perfectly as the nervous influence for which it had been substituted.

This seemed sufficiently to determine the point at issue, the nature of the nervous power. But it was a necessary inference, that if the nervous power be galvanism, it is not a power peculiar to the particular structure of the nerves, and ought therefore to be capable of existing elsewhere. After many vain attempts made with a view to cause the nervous power to leave the nerves, and give evidence of its presence elsewhere, this was at length effected by experiments, the accuracy of which has been ascertained by repetitions both in this country and on the continent.

This fact, in combination with the results of those experiments in which galvanism was found capable of all the functions of the nervous power, the most essential of which have also been repeated both at home and abroad, removes, as far as I am capable of judging, all doubt respecting the identity of the two powers. Thus the living animal body possesses the sensorial and muscular powers peculiar to itself, and the nervous power of which it partakes in common with inanimate nature.

In attempting to trace the laws of the two first, therefore, it is in vain to expect assistance from any other source. But if the view here taken of the nervous power be correct, it necessarily follows, that many analogies must exist between the effects of that power and the phenomena of inanimate nature, and that many of the inferences from the latter will be found more or less applicable to the former. The operations of the same power, however different the circumstances under which it

* See the statements in my first communication to the Editor of the Medical Gazette, the paper just referred to in the Philosophical Transactions for 1829, and the third edition of my Inquiry into the Laws of the Vital Functions.

* My Inquiry into the Laws of the Vital Functions.

operates, must always have much in common; and, in fact, we find that all the analogies which can be traced between the phenomena of the living animal and those of inanimate nature, belong to the phenomena of the nervous power.

Where shall we find in inanimate nature any thing analogous to the circulation of the blood, or any of the other effects of the muscular power, and still less can we look for any thing analogous to sensation, volition, or any of the other functions of the sensorial power. But when we turn to the phenomena of the nervous power, many analogies with certain phenomena of inanimate nature, force themselves on our attention; nay, there are none of its functions in which such analogy may not be traced; a circumstance from which alone the similarity of their origin might have been suggested.

The nervous power, in its impressions on the sensorium, in its excitement of the muscles, in all the chemical changes it effects in the formation of the secreted fluids, the preservation of the healthy structure of all parts of the body, and the maintenance of animal temperature, nay, in its very generation and mode of conveyance, bears a striking affinity to that world with which the living animal is in so many ways associated.

But such is the difference of the circumstances in which galvanism operates in the living animal and elsewhere, that, however striking the analogy, the results cannot be identical. We have seen it proved, that galvanism operating in the living animal under the same circumstances as the nervous power operates, produces the same effects; but it is only under such circumstances that its effects are, or, on any principle, can be expected to be the same; and any inference respecting the functions of the living animal from the phenomena of inanimate nature without regard to these circumstances, must necessarily be erroneous.

Of all the chemical powers with which we are acquainted, galvanism is the most energetic, and for this reason doubtless is employed by nature in certain functions of the living animal, where the chemical changes are at once the most rapid, the most varied, and the most complicated; but here, as in inanimate nature, its effects, as appears from what has just been said, are not confined to chemical changes; and

whether chemical or not, they are influenced by, and some of them wholly dependent on, its association with the more strictly vital powers.

Thus its chemical operations are such as no unassisted chemical agent can produce, and many of its other effects differ essentially from, and bear but a faint analogy to, any of those which belong to inanimate nature. It is the medium of the sympathy which exists in the different parts of the living animal body. It is the bond which connects them together, and thus forms them into a whole. It is through the nerves, for example, that an offensive body introduced into the trachea or the stomach excites the motions which expel it; that the obstructed skin excites the heart and bloodvessels by their increased action to remove the obstruction; and so on in a thousand other instances.

On carefully reviewing what has been said, we may form a pretty just estimate of the extent to which, and the modifications under which, chemistry is applicable to the functions of the living animal.

In the functions of the sensorial and muscular powers it has no place. Can it move a limb, or propel the blood, or perform the slightest act of the sensorium?

In part, and but part, of the nervous functions it has place. These, it will readily be admitted, are an important and extensive part of those functions; but even here its effects are essentially modified. The chemistry of the nervous power is not the chemistry of inanimate nature. We know that the changes are effected by the same chemical agent, because we have seen them all effected by that agent; but in the animal economy its effects are modified by the vital powers with which it is there associated.

The chemical effects of the nervous power are not only, in a manner analogous to its other effects, modified by the vital powers, but also in a way peculiar to themselves; which, even were the chemical laws of animate and inanimate nature the same, would greatly increase the difficulty of applying them to the functions of the living animal. In the processes of secretion and assimilation it is not only impossible for us to trace the steps by which the changes are effected, which compels us to admit the operation of certain causes peculiar to the living animal, the effects of

which, consequently, we can never even hope to see exemplified in inanimate nature; but the results of the chemical processes of the living animal, unless the resulting substances be immediately removed from the sphere of action of the vital powers, are so constantly influenced by them, that, in a large proportion of instances, even were we acquainted with every chemical change which takes place, it would be impossible to say what change is effected at any particular moment of its complicated and ever varying processes; and this difficulty is still farther increased by our very attempts deranging the natural process, by necessarily introducing a set of causes which are foreign to it. If, for example, we wish to ascertain the changes effected on the blood by respiration, the very circumstance of removing it from the vessels, as I have found in repeated trials, unless our experiments be made while it is flowing from them, causes the most essential change in its chemical properties. Yet this is a favourable instance—we can obtain the blood in the state and at the moment in which we wish to examine it. In most of the assimilating and secreting processes, it is impossible for us to determine the moment at which any particular change takes place; and if we could determine it, by what means shall we, at that moment, submit the subjects of these processes to our tests?

When, to the whole of these circumstances, we add, as I pointed out at length in a late communication, that the chemical changes take place chiefly in the fluids of the body, whereas it is chiefly on the state of the solids that the great changes of the animal system depend, that of the fluids constantly varying as their state varies, we readily see how limited must be the application of mere chemical principles either to elucidate the functions of the animal body in health or restore them when they have deviated from it.

Such is the view of the subject which our knowledge of the animal economy, deduced from observations and experiments made on the healthy animal, affords; and this view is amply confirmed by all our experience of its diseases. Let us take our illustrations from those with which we are most familiar.

Has not the chemical composition of the bile been long known to us? Has this knowledge assisted us in correcting

its derangements? If we could exactly ascertain the nature of its derangement in each particular case, and could find a chemical agent capable of correcting it, would it afford any permanent relief while the diseased action of the liver continues? On the other hand, if we look to the means which experience has taught us are most effectual in correcting diseased states of the bile, do we find any particular relation between these means and the morbid states of the bile corrected by them? They do not act by correcting the morbid states of this fluid, but by improving the function of the organ which secretes it.

The vitiated state of the bile already formed, no doubt occasions certain symptoms which aggravate the evil. In its passage, it irritates the surface of the alimentary canal, and as far as its morbid properties can be corrected, this irritation will be allayed; but being once discharged from the liver, it has no more to do with the morbid action on which its vitiated state depends, than any other equally irritating substance introduced into the same passages would have; and while it is being formed, as its vitiated state is the consequence, not the cause, of the disease which has deranged it, its correction, even at the moment of its secretion, were this possible, could not correct that disease.

Let us take another familiar instance, which is the more in point because the imperfect knowledge of our predecessors respecting the laws of the animal economy actually led them to practise on the mere principle of the chemical properties of the remedy. Putrid fever takes its name from the putrid state of the various secreted fluids; and such was their confined views of the animal economy, that they thought, if the putrescent state of the fluids could be corrected, nothing more would be required for the cure of the disease; thus mistaking a consequence of the disease, the necessary effect of the failing powers of life, for the disease itself.

The trial was fairly made, for at one time no physician would have been considered as doing his duty if he had, in such a case, omitted the use of antiseptics; and what has been the result? that any physician who should now place reliance on them, although the labours of the chemist have supplied us with such as are far more efficacious than any possessed by our predecessors,

would only expose himself to the animadversions of his better-informed associates. It would be superfluous to pursue the subject farther, as I have already had occasion to observe the tendency of such views is to bring us back to the humoral pathology—a pathology equally narrow and mistaken, which could not for a moment have existed except in the very infancy of our science.

Are we, then, it may be said, to regard chemistry as wholly inefficient in tracing the laws of the living animal body, and enabling us to cure its diseases? Such a question could only have been suggested by the exaggerated claims which have been made in its favour. Its legitimate claims in these departments of knowledge, notwithstanding all the deductions which have been stated, are great. They are sufficient to satisfy the most ardent admirer of a science which has left so few branches of knowledge indebted to it. Let us take a rapid view of these claims, and first as respects physiology.

Although chemistry cannot, and, for the reasons which have been mentioned, never will, enable us to trace all the changes of composition which take place in the living animal body, physiology is in many respects indebted to it. It can tell us many of the changes of composition which take place in the living animal, and all those which the living animal effects in the external bodies influenced by it. It can explain, for example, certain changes in the blood effected by respiration, although it cannot explain all these changes, and of all the changes effected by respiration on the air, it can give us a perfect knowledge. Thus we owe to chemistry all the knowledge we possess respecting one class of the effects of this important function.

Similar observations apply to the function of perspiration, which, like respiration, both influences the composition of, and, under different circumstances, variously impregnates, the air.

In like manner chemistry, although incapable alone of explaining any stage of the process of digestion, can determine many of the changes which the food undergoes in that process. Although we have reason to believe that the chyle, when taken from its vessels, is not in all respects the same as that which moves in them, chemistry can, by enabling us to compare its compo-

sition with that of the food, determine many of the changes effected in the latter.

To chemistry we also owe our knowledge of many of the secreted fluids. These are separated from the living powers by being discharged externally, or into the various cavities of the body, and are therefore no longer subject to their influence; and their composition throws much light on the nature of the general, if not on the detail of the particular, processes by which they are formed. It tends also to throw no small degree of light on many of the functions of the animal body, that chemistry has unfolded to us the changes which would take place in the substances of which it is composed, were they not counteracted by the vital powers of that body. Many of the changes which take place in disease are of this nature, for as these powers fail, the laws of inanimate nature begin to prevail over them, and, before the patient expires, the latter have often in a great degree established their dominion, producing symptoms which cannot be explained without a recurrence to those laws. This leads us to the second part of the subject.

If the science of the vital functions in a state of health has been indebted to chemistry, that of their diseased states has been infinitely more so; not only as a means of occasionally explaining a certain class of the phenomena which attend and modify these states, and thus occasionally suggesting means of relief; but in giving the most efficacious and convenient form to a large proportion of these means. Respecting the first part of the subject, we cannot have a better illustration than Dr. Prout has afforded in his investigations respecting urinary diseases. These diseases, I have already had occasion to observe, are particularly favourable to the labours of the chemist, because many of their most distressing symptoms depend on the state of the urine which is so long retained after its secretion, forming no longer any part of the living animal, and acting in the same way and being subject to the same changes as would be the case with respect to any similar fluid introduced from without.

In cases of other deranged secretions, and those of morbid extravasations and growths, we have derived much information from the labours of the chemist; and those acquainted with the

progress of knowledge will not undervalue such information, because, in many instances, it has not yet led to practical results.

When we turn to the improvement of the medicinal part of our means of cure, we owe every thing to chemistry. On this subject it would be superfluous to make many observations: it is the peculiar province of the chemist. In the various pharmacopœias, and the works published with a view to illustrate their processes, we see how much we are indebted to him. To the improvement of this important branch of knowledge chemists of the highest character have lent their aid. To the French chemists we are particularly indebted, and not less to some of our own countrymen, who have devoted to it a large proportion of their time and labour. We have been supplied with many new means of relief, and many of our former means have been rendered both more congenial and more efficacious.

ASTHMA, &c.

The Case of Mr. George Hobson, of Great Marylebone-Street, drawn out by himself.

MR. HOBSON, aged 60 years, a native of the North Riding of Yorkshire, where he resided till he was 21, was subject, from early youth, to violent attacks of asthma, which were almost regularly periodical, occurring once in six or eight weeks. They varied as little in their frequency as in their violence, and each fit continued six or seven days, during which he could never lie down nor breathe unless his legs were in a depending position, nor sleep except with his head on a table placed before him; after this, easy and copious expectoration came on, which, continuing for three or four days, completely relieved him from every embarrassment. He continued thus dreadfully to suffer from the age of seven to twenty-one, when he came to London, and remained upwards of eight months, during which period he never experienced even difficulty of breathing; and though he had, from frequent attacks of cold, violent coughing and its other usual attendants, his asthma did not return. He revisited the north, but be-

fore he reached home was attacked with his old enemy, which continued for four months, without any complete interval of ease, and the paroxysms were more violent than formerly. He then determined upon returning to town, where, being of the medical profession, he settled, and has since remained, without ever being deprived of a night's rest from asthma, though he has had, in severe colds, more than ordinary difficulty in respiration. In three or four years after the asthma left him, he became subject to irregular action of the heart, and palpitation, attended with great flatulence and acidity of stomach, and he fancied himself relieved by alkaline medicines, and particularly by the carbonate of ammonia, from its cordial effects in large doses. The attacks were at first of short duration, but soon became more serious and frequent, and have continued without intermission for eleven or twelve hours, attended with a violent and indescribable pain along the whole course of the spinal column and under each scapula, and difficult and painful respiration; the whole of which deprived him, at the time, of the power of walking without support. He can only compare his feelings to what would be the result of an immense weight placed upon each shoulder, dragging them and the scapulæ down. These symptoms were attended and followed, for some time, with a sighing laborious respiration, much increased upon the slightest exertion, and a sense of numbness and pain extending down both arms, particularly the left. The digestive functions were at times a good deal disturbed; the secretions of the liver and the bowels much depraved; bowels regular; motions dark and offensive; appetite very good; sometimes, but not often, vomiting after meals; his general rest at night but short, and disturbed. The period during which these attacks were absent was very irregular; sometimes as many as four or five times in one week, at other times he had not one in two months. Whenever dyspepsia attended, the usual remedies have always failed to cure it. The affection of the heart, however, came on in the intervals, and just as much when the nutritive functions were well as when they were imperfect; and he was at all times pale, debilitated, and bloated, with œdema of the feet and legs, extending to the knees, and moved

about with difficulty; and such was his state of health, that, for four years past, he has never left home without having his name and address in his hat or a card in his pocket, being doubtful if he would ever return alive. It was soon after his arrival in town, about thirty-four years ago, he became the subject of irregular action of the heart; this, at first, was but slightly noticed, but soon became of a more pressing and alarming nature; the seizure would come on without any sign or note of its approach, when either sitting, lying in bed, or in active exercise; four or five of the heart's pulsations could not be felt; the fifth would be an irregular bound against the parietes of the chest; there was no distinct or regular interval observable in the pulse — its rhythm would be nearly continuous against the finger; there was an oppressive constriction across the chest, coldness of the extremities, numbness and pain in the arms, as before noticed; the face expressive of intense anxiety; nose and lips cold, and of a blue colour; great restlessness, and inability to remain in one situation; frequent windy evacuations, without any apparent relief. The only thing which appeared to afford ease was the employment of strong friction along the course of the spine. These phenomena lasted indifferently for two, six, or twelve hours (never so violent, however, when so long as the latter period), when, with a sudden and very forcible and painful impetus against the ribs, the heart would be righted, and its action, with that of the pulse, would at once become regular. From the long continuance of these attacks, and frequent recurrence of irregular action of the heart, he was led to believe the existence of some structural disease in or about the heart; in which he was confirmed by the opinion of medical friends, many of whom he consulted, and by his father having suffered in the same way and died very suddenly.

Dr. Wilson Philip was at this time (about a year ago) consulted; who afforded him great consolation by assuring him that there were good grounds to hope that, in a great measure, his fears were unfounded, and, as many of these appalling symptoms were evidently sympathetic, there was reason to hope that the others might be of the same nature. Dr. P. ordered him five grains of the blue pill for three alternate nights, with

an aperient draught on the following morning. The alimentary canal was thus cleared, and Mr. H. by his advice, commenced taking half a grain of blue pill with three of Extr. Hyoscyamus, three times a-day, with stomachic draughts, and other occasional treatment; which he continued for many months, and which, he believes, has restored him. At first the relief was less perfect, and only occasional; by degrees the intervals of relief became more perfect, and of longer duration, and it is now four months since he has had any attack; while his looks, feelings, and general health, are in every way so much improved as to surprise those who have known him for the greater part of his life. His œdematous swelling and bloating have disappeared, and he has regained both the appearance and habits of health.

October 10, 1831.

OVARIAN DISEASE.

To the Editor of the London Medical Gazette.

SIR,

MRS. BOTTRELL, æt. 24, of short stature and light complexion, married four years. Has had no children, nor abortions; until a year and a half ago enjoyed good health. At that time was attacked with inflammation in the left iliac region. In a few days it was so far subdued that nothing but a slight pain and uneasiness remained. In a few weeks the abdomen was observed to be enlarged, and continued to enlarge for four months, when fluctuation was discovered. The operation of tapping was resorted to, and was repeated four times previously to her being under my care. What remedial means had been employed, I am unacquainted with. After the second operation the abdomen was noticed to be still large, and on examination a tumor was detected in the pelvic region. I was called upon to perform tapping on February 24th, 1831. About four gallons of limpid fluid were removed. After the operation the lower part of the abdomen remained prominent, and the parietes were distended; it had an even surface, and conveyed to the touch a doughy feel; no tenderness or pain on pressure; the body was much emaciated; tongue furred; appetite bad;

bowels torpid, and secretions dark-coloured; urine pale for a few days after tapping, but became thick and albuminous; pulse 120, small and thready; skin dry and hot; sleep disturbed; shooting pains along the course of the large nerves of the thigh.

Purgatives, mercury, and the various diuretic medicines, were exhibited. The Tr. Iodinæ was given for a few weeks, commencing with five drops every four hours, and increased to five and twenty. The abdomen was rubbed twice a-day with an ointment composed of Ung. Hydrarg. and Camphor. Digitalis was given to diminish the frequency of the pulse, which it did effectually. The general health became improved, but without any diminution of the tumor, and only slight retardation of the dropsical accumulation. The Ung. Hydriod. Potassæ was rubbed into the abdomen for the space of half an hour twice a-day, regularly. The circumference of the abdomen after tapping was found to have diminished three inches and a half in eight weeks from the commencement of the Iodine friction. Paracentesis abdominis was repeated every three weeks or a month. The fluid varied in colour each time; sometimes it was limpid and watery, at others thick and opaque, and containing in it flakes of lymph and pus. At one time about a quart of uncoagulated blood followed the withdrawal of the trocar. On the 5th of September the last operation was performed. Seven pints of fluid more than previously, were removed. The day following she was up, and would, injudiciously, be assisted into the yard; she sat there for half an hour, but on account of faintness was obliged to return. From that time complained of soreness in the abdomen, not tenderness on pressure, nor positive pain; she said it was an indescribable uneasiness. Peritonitis being suspected, the various antiphlogistic measures were promptly adopted, but without affording any relief. On the 19th she died*.

Ovarian disease is universally allowed to be one of those direful maladies which have hitherto baffled every attempt at their removal by medicine. Happily this disease is not of very frequent occurrence; and to this may be

fairly attributed our ignorance of any true diagnostic marks by which it can be recognized in its early stage. On reviewing the preceding case, many circumstances present themselves importantly interesting. We observe that this disease occurred in a *young* woman, who, though married, had never borne children; that it commenced with inflammation in the left iliac region; that in *four months* the abdomen was filled with fluid; and that the tumor was at this time so diminutive, that its existence was not even suspected. But one of the most remarkable features was the rapidity of the growth of the tumor, it not being cognizable immediately after the first tapping, yet in six weeks being as large as a child's head.

Had the tumor been discovered when the size of an orange, or even *twice* that size, would extirpation of it have been practicable?

The question is answered by that philosophic physician, Dr. Blundell, in his *Physiological Researches*; where he has proved very satisfactorily the groundlessness of the fears entertained with respect to wounding the peritoneum, and has also shewn the facility with which diseased ovary, in its *early stage*, may be removed. In this case it is obvious that extirpation could have been successful only in the very earliest period, in consequence of the early formation of the dropsical sac; yet I believe no one would have apprehended that such a structure did at the time exist. Even at the period when I first saw the patient, and also during the whole of my attendance, I did not doubt that the dropsical fluid was contained in the peritoneal bag. Dissection revealed that it was not; but that it was contained in a new structure, the 'sac,' which sac must have been formed either prior to the enlargement of the substance of the ovary, or have increased in a much greater ratio, so as to have lined nearly the whole of the abdominal cavity—to have become filled with fluid, and to have existed so for some weeks before the tumor was discovered.

We observe the inefficacy of the most potent medicines in this disease; and it affords further corroboration of the veracity of the conclusion, that on such morbid structures medicine has no influence. We therefore arrive at the inference, that extirpation of diseased ovary, in the *early period of its growth*,

* We omit the postmortem examination, as the appearances were not unusual, and as we are much pressed for space.

is the only curative measure we are yet acquainted with.

Ought paracentesis abdominis to be performed in ovarian dropsy, when the fluid does not amount to more than *thirty-two* pints? What advantage can accrue from such early tapping? Will it prevent a future accumulation?

Should any urgent symptom arise, such as violent dyspnœa, then the operation of tapping might be demanded; but it does not appear that in this case any unpleasant symptom was manifested;—she was tapped because the abdomen was filled. It is clear that no permanent benefit can be obtained by early tapping; for, while the cyst remains, fluid will be again secreted, unless the sides of the cyst could be retained in coaptation, and inflammation induced, so as to obliterate the cavity; but it would be difficult to effect this, owing to a certain quantity of fluid which must necessarily remain and form a nidus.

With respect to the tumor there can be no doubt that it was a disease of the ovary; but under what genus it can be classified, it would be difficult to say. It is neither a scirrhus, nor an hydatid, nor yet a common encysted tumor; but a combination of the three structures. The cells could not all be the enlarged vesicles of De Graaf, because these are not more than sixteen or twenty in number; whereas some hundred cysts were discovered, many of which had all the characters of hydatids; it is probable that the 'vesicles' were implicated. The envelope of the tumor appears to have been the *tunica propria* of the ovary; and the 'sac' an extension of the upper border of that tunic, which had become separated from the contained parts.

These brief remarks may enable the reader to comprehend more clearly the nature of the case.

I am, sir,

Your obedient servant,

W. DOBSON, Surgeon.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Observations on Cholera, as it appeared at Port-Glasgow, during the months of July and August 1831. Illustrated by numerous Cases. By JOHN MARSHALL, M.D.

DR. MARSHALL, of Port-Glasgow, is the gentleman who created a somewhat unnecessary alarm some months ago by reporting to government the occurrence of cholera in the town where he resides. It soon appeared, however, to use a vulgar expression, that he had "found a mare's nest," and some degree of ridicule, naturally enough, followed this discovery; in fact, we imagine from the contents of the brochure before us, that the Doctor's cases had become a standing joke in the north. Instead of letting the matter drop quietly and be forgotten, Dr. Marshall resolved to print the cases, "and shame the rogues." This proceeding, we think, was injudicious; for, in our opinion, he has thus condemned himself out of his mouth. Twenty-four cases of vomiting, purging, with cramps, &c. are related, such as every man occasionally meets with in the hot months; of these only one died, and he had been drinking some days before at an Irish wedding, and at the onset of his attack, before Dr. Marshall was called in, had had a mixture, containing six grains of tartar emetic. The Doctor does not admit that he had taken much of this, but adds, "Let us, for the sake of argument, allow that the whole was swallowed at one draught, could these six grains of emetic tartar have produced the morbid symptoms (namely, excessive depression, vomiting, purging, &c.) which I witnessed when called to him nineteen hours after?" The practitioner who can gravely ask such a question, must be wonderfully ignorant, or have his ideas strangely perverted by prejudice.

We shall quote one of Dr. Marshall's cases, selecting one which was severe, but the account of which is conveniently brief:—

"July 11, 1831.—James M'Lachlan, ætat. 25, labourer in a sugar-house, very stout made, enjoys excellent health, was seized during the course of

last night with deadly sickness, vomiting, and purging of dark matters, which speedily changed to colourless fluids, excruciating pain in the bowels, spasms, by which the abdominal muscles seemed drawn in till they rested on the spine; excessive debility; surface of body cold; profuse cold perspirations. Reaction took place in eight hours after first attack; was completely established in twelve. The patient convalesced rapidly, and returned to his work on the 15th.

"Had sat with John Murray during the night of the 3d July; knows of no other cause for his illness; has not partaken of fruit, vegetables, or 'new potatoes,' during the present season."—*Ex uno disce omnes.*

Illustrations of Surgical Anatomy, with Explanatory References; founded on the work of M. Blandin. By JOHN G. M. BURT, Surgeon to the City Dispensary, Extraordinary Member of the Royal Medical Society, &c. 4to. Edinburgh.

These illustrations of surgical anatomy are founded on the justly-esteemed work of M. Blandin, on whose plan, however, the editor has improved. In the fasciculus which lies before us there are two plates, the first representing the superficial and the second the deep-seated anatomy of the neck. They are beautifully executed, and if those which follow equal them in this respect, the work will prove highly creditable to Mr. Burt, and extremely useful to the practical surgeon as well as to the student of anatomy.

Pharmacopœia Medico-Chirurgica in usum Medicinam Facientium, à ROBERTO G. HOLLAND, Chirurgo, Concinnata.

This volume contains a certain number of lists of medicines, tables of synonyms, formulæ, &c. perhaps as good, certainly no better, than many others previously published.

Reports of Medical Cases. By DR. BRIGHT. Price 9l. 9s.

[Continued from page 57.]

Inflammation of the Substance of the Brain.

The next subject which attracts our attention, in the regular order of the volume, is inflammation of the substance of the brain.

A healthy man, nearly sixty years of age, fell, and slightly scraped the side of the left temple. He found it very painful, used common remedies, and in a day or two had forgotten the accident, and returned to his usual avocations. Three weeks after he went upon a shooting excursion, took much exercise, got wet, eat heartily, and slept into a coach to return to town. During the journey pain in the head came on, and by the time he arrived at home he was labouring under a smart attack of fever, with pain spreading from the eyebrow towards the vertex, and occasionally down the back. He was bled generally and locally, and had appropriate remedies to allay the febrile disturbance. Next day was much the same, perspired freely, and became chilly on the least exposure; his manner was hurried; in fact, he was slightly delirious. There was puffiness above the eyebrow, and a tumor in the socket below the eye, from which last some discharge of pus took place at night, with great relief. On the following day, the symptoms continuing, he was seen by Mr. Brodie, who cut down upon the bone just above the superciliary ridge; it was rough; about "three drops" of pus came away, and the patient was "in heaven." He went on for some time without any very decided change, afterwards became rather childish, being, however, at intervals, more rational. For several days he got up regularly for a few hours, though his pulse was extremely weak. He was now seized with an erysipelatous attack of the face and head, which carried him off in a week.

"*Sectio Cadaveris.*—Some serous effusion in the cellular membrane of the scalp. The bone was denuded only to a small extent, about the size of a sixpenny piece, where the second opening was made; but the surrounding bone, more particularly between this opening and that which had been made upon the superciliary ridge, was unusually brittle, splintering in various directions under the saw and the chisel. The pericranium just round the denuded bone was thickened. The dura mater was not detached, but a deposit of organized membrane, nearly as thick as the dura mater, but more flocculent, had taken place between it and the bone in that part, over an extent of the size of a crown piece; and a mark remained upon the bone where the deposit had chiefly been, of an irregular form, with white specks as if from adventitious matter deposited in the pores of the bone. When the dura mater was raised,

its internal surface shewed also a flocculent deposit, and the whole surface of the brain exhibited the arachnoid raised by serous effusion, so as to conceal the convolutions; the arachnoid was slightly opaque; but on the edge of the anterior lobe of the left hemisphere, close to the falx, was an ulcer of the size of half a hazel-nut, oval, depressed, and containing a small quantity of turbid white fluid, of puriform character; and when this was removed with a sponge, a clear depression became visible, as if a piece of the brain had been cut out. The brain itself did not appear unhealthy, but the blood was rather fluid in the vessels divided in the cerebrum, giving bloody points. In the ventricles was at least double the ordinary quantity of serum, and that rather turbid. The choroid plexus was natural, nor was any other obvious deviation from health to be discovered."

Although the above be adduced as a case of ulceration on the surface of the brain, Dr. Bright is not disposed to argue that the chief symptoms depended upon this.

A man of colour, between fifty and sixty, was admitted at Guy's with severe dyspnœa, and dropsy. He had been in the hospital before, for the above symptoms, but had been sent away "on account of the noise and disturbance he made during the night." He was now in a drowsy state, capable of being roused, but not so as to give any satisfactory account of himself. He was not considered as being in his sound mind, and at night became noisy. About four days before his death he was observed to be sinking, but his pulse always had a peculiar sharpness. There were some appearances of slight paralysis.

"*Sectio Cadaveris.*—On removing the dura mater, a thin layer of effused blood of several inches in extent—in some parts as thin as paper, in others in flat masses as thick as a shilling—was discovered on the posterior part of the left hemisphere, and on the anterior part of the right; this was not effused so as to be smeared over, or to discolour the arachnoid, but remained attached to the dura mater, and could be peeled off as if the thin clots of which it was composed were contained within a membrane; but whether this was only a fibrinous envelope of the clot, or an actual membrane, was doubtful. I inclined to the latter opinion. On examining the base of the brain, both of the anterior lobes were found to be eaten by superficial ulceration in three or four irregular patches of the size of a shilling, which were yellow and excavated to the depth of the eighth of an inch, though the yellow soft matter could scarcely be considered as true pus. The vessels of the base were not

perfectly healthy, but in different parts contained cartilaginous deposits. On the surface of the medulla oblongata was a curious black carbonaceous deposit, following somewhat in the course of vessels, which, judging from some other cases, I believe to be the remains of a former effusion of blood under the arachnoid, or upon its surface.

"The left lung was partially adherent to the pleura, containing much grey matter, natural in structure, but loaded with serous effusion. The bronchial tubes of the deepest red colour, and much dilated towards their extremities. The right lung much more generally adherent, and extensively hardened, from old and chronic inflammation; so that scarcely any part performed its functions: the upper lobe, in particular, was a hard, tough, grey mass, and the bronchi were still more diseased than in the left lung."

In this case there were sufficient signs of some derangement of the brain, but this was conceived to depend chiefly on the difficulty of transmitting the blood through the lungs.

Cases follow in which encysted abscesses were found in various parts of the brain; in some of them, from external injury, in others from spontaneous causes: but as these cases do not appear to us to present so much interest, either in a pathological or practical point of view, as most of the others, we shall pass on to

Cases illustrative of softening of the Brain;

that peculiar change of structure which has been of late years described by some of the most distinguished among the French pathologists, as well as by some among ourselves. Dr. Bright is of opinion that "softening" of the brain may exist in various forms, may originate in various causes, and may be marked by different symptoms. The symptoms, however, which generally first attract attention, are those of pressure: for the most part they come on suddenly, and they vary in their progress and duration. The pressure, however, seems to be but a secondary part of the diseased condition—a consequence of some change which has gone before it; while it throws but little light on the nature of the pathological condition.

The first case detailed (LXXXI.) is one in which there was sudden hemiplegia, all power of voluntary motion and all sensation being lost both in the upper and lower extremity. The face was only slightly affected, but the speech was exceedingly imperfect. Pulse 68,

weak. This man had married a woman much younger than himself a few years before. He had also been subject to an open ulcer on the leg for several years, but which had healed up about six or eight months before. He then became subject to attacks of diarrhœa. He had never complained of his head. He was admitted August 5, and died on the 21st of the same month. Post-mortem examination discovered softening of the middle and posterior lobes of the left hemisphere of the cerebrum, with limpid effusion beneath the arachnoid and between the convolutions.

A man, aged 30, was admitted at Guy's Hospital, April 7th, with imperfect hemiplegia and coma. It appeared that he had complained of the left side of his head for three or four months, and just four weeks before admission he had been seized with very severe headache, which had continued ever since. The loss of power came on gradually. On the night between the 5th and 6th he became worse, and passed his fœces involuntarily, losing his speech at the same time. He lingered till the 21st. Softening was found of the anterior lobe of the left hemisphere. The arteries in the vicinity of the fissura Sylvii were indurated and cartilaginous, and the circle of Willis was studded with bony deposits.

A young man, aged 28, was admitted October 4, 1827, with partial paralysis, marked by slight deformity of the face, and feeble, unsteady action of the arms and legs. Had from infancy been afflicted with headaches, generally referred to the forehead, with occasional giddiness. The symptoms increased about three years ago, and about eighteen months since had a fit, in which he lost his senses for a few minutes. There was a very gradual, but decided change, from this time, indicative of chronic mischief in the brain. He died on the 12th of November. Great vascularity of the pia mater was found, with softening of the left hemisphere in two places.

A gentleman, aged 73, was suddenly reduced from comparative affluence to penury by the knavery of a partner, who absconded. On receiving the information, he fell down in an apoplectic seizure. After a time he recovered from this attack, and was able to write for one of the weekly journals, although his memory was defective. In ten

months he had a second fit nearly like the first; after this he never was able to engage in any occupation, and about three weeks before the date of the report, he had a third fit, for which he was copiously bled, and had some aperient medicine. After this he was at times tolerably sensible, but in general lay in a comatose state, and appeared to have lost all power in the right hand as well as in both legs. He continued much the same from the 24th of June to the 3d of February following, when he became more conscious, and had more power over his limbs. This improvement lasted three or four days, when he sunk into a comatose state, and died on the 9th. On examination after death, considerable cerebral congestion was found, with partial softening, especially of the fornix and septum lucidum. There was a good deal of fluid about the brain. Dr. Bright observes of this case, that it was probably one of those in which no considerable vessel is ruptured, the apoplectic fit rather depending upon a general state of congestion, producing slight laceration of the fine vessels, chiefly at the union of the cineritious with the medullary matter.

A tall, athletic man, 40 years of age, was admitted at Guy's, under the care of the author, January 21, 1829. He had been long in the army—had received many wounds, and had "scars to shew." He laboured under great depression of body and mind; his left arm and leg were weakened; his gait unsteady; and he squinted. "His manner was peculiar, and his conversation quite incoherent; he stood for some minutes together in one position, as if lost in abstraction; when spoken to, he answered a question with some consideration apparently correctly, but then at once ran on to something else, without however saying much, but making some statement perfectly without foundation; as, for instance, saying that he was bled this morning, that the blood flowed well, and did him a great deal of good;—all which was most distant from the fact." His illness had been coming on about a year, and the first indication of it was his falling down in the street, and losing his recollection for a moment. This happened repeatedly, but was equally transient as at first. He had, however, constant pain in the forehead, and for the last six weeks had passed his urine,

and sometimes even his faeces, in bed. He now had leeches applied, a seton was introduced into the neck, and he was purged. Afterwards he took a grain of sulphate of zinc three times a day, and the quantity gradually increased to gr. v. ter die. Carbonate of iron, sulphate of quina, and various other means, were tried without avail. July 10th he is thus described:—"His general manner and aspect quite unchanged; he stands about musing; and if you ask him how he finds himself, answers, after a few seconds of consideration, 'I am not quite dead;' says he has hurt his thigh, and that there are wounds in two places; but on examination there are only two old scars from wounds he had received in service; he complains of weakness of the whole left side, but then says he feels rather better."

He died on the 23d. The skull shewed a slight irregularity, with depression of half the size of a sixpence, with a minute point of bone running towards the brain: this was at the site of a wound. The chief morbid appearance was in the corpus striatum of the right side, which was quite flattened, and of a yellowish colour: it felt quite soft, and on making a section was found to be completely broken down, having a "filamentous and watery brown appearance."

The author, in commenting on the cases of which we have above given a brief outline, observes,—

"Thus we perceive that partial softening of the brain probably owes its origin to a variety of causes, and to a considerable range of morbid action; and we may therefore conclude, that however much the symptoms of the confirmed disorganization may approach in all cases, and may generally evince proof of pressure, and of interrupted nervous susceptibility and action, yet that the symptoms which mark its progress and approach will vary greatly; and this conclusion will be borne out by a comparison of the symptoms in the cases to which I have had occasion to refer. Although it is possible that inflammation may exist without being attended by very striking symptoms, yet I am inclined to make a threefold division of cases in which a softened condition of portions of the brain exists. First, where from obstructed circulation the part undergoes a change analogous to gangrene; and this is the more ge-

nuine form of the disease (Case LXXXI. LXXXII. LXXXIII.) Secondly, where from congestion the substance of the brain suffers a more or less complete laceration (Case XXIV. LXXXIV.); and under this division might be classed all those cases in which the disorganization is secondary, and to a certain degree mechanically dependent on the presence of tumors, or effused serous fluid, or apoplectic clots (Case LXV.) And thirdly, where softening is produced by inflammatory action (Case LXXVIII. LXXIX. LXXX.)

"It must however be remarked, that in these observations I speak only of partial softening with disorganization of the brain; not including those cases in which the whole substance of the brain is found unusually soft, a condition which often occurs when the body has been greatly debilitated and worn out by disease, but seems not to interfere with the structural integrity of the organ.

"Dr. Baillie, in his incomparable manual of morbid anatomy, by which the attention of modern physicians was chiefly drawn to the study of pathology, speaks of the softening of the brain as it is described more particularly by Dr. John Hunter, in the *Gulstonian Lectures* read before the College of Physicians in 1796; and he refers to its occurrence under two forms—in advanced age, and combined with apoplectic effusion; though, by a remark he afterwards makes when speaking of the effusion of blood into the brain, it is doubtful whether he considered it in the latter case a disease existing previously to the rupture of the vessels, or a consequence of the mischief. The fact appears to be, that it occurs in apoplexy under both of these circumstances, and cases illustrative of both will be found recorded even in the present volume.

"With regard to the treatment of cases in which we are induced to suspect that the softened disorganization is taking place, it will of course vary according to the cause; as long as we are obliged to infer excessive action we must deplete, and use counter irritation; but looking to the general condition of those who are the subjects of such disorganization, we should be inclined to prohibit active depleting remedies, as likely to diminish the powers of the system. Nor can we suppose that the mercurial action would produce any

good effect; on the contrary, whatever is calculated to disturb the more healthy and natural actions, may be expected to do harm, and probably the careful avoidance of every thing which can over-excite either the body or the mind, with the employment of gentle tonic remedies, both as medicine and as diet, and even as occupation and amusement, will be most effectual in delaying the mischief, or in supporting the frame under its gradual decline. To what period life may be prolonged, when a considerable extent of the substance of the brain is diseased, we have not the means of asserting; but that large portions of the brain may be lost with apparent impunity has been proved in many instances; and in some of the foregoing cases there is reason to believe that the mischief had existed several months, attended, however, with great functional derangement. Whether healthy brain be ever regenerated is very doubtful; but as to the power of nature of repairing in some degree the injuries of the brain, there can be no doubt; and there is reason to believe, that parts of the substance which have been lacerated by blows, or by apoplexy, and thus rendered useless, are frequently absorbed; but how far the powers of the system are sufficient for such an operation, where, as in the cases of Kennedy or Murrledge, spontaneous change has taken place, remains a matter of speculative opinion; at all events, one of the best objects we can propose in the treatment, is to give force and vigor to those natural actions by which such reparations are effected."

PRESSURE.

The division of this part of the subject adopted by our author, is, first, into those cases which illustrate the effects of mere vascular turgescence; 2dly, those in which the symptoms appear to have been in some degree, at least, the result of effused serum; 3dly, cases in which there has been rupture of vessel, with extravasated blood; and 4thly, those in which the pressure has resulted from some organic change.

Cases illustrative of the effects of Cerebral Pressure from Vascular Turgescence.

When this state comes on suddenly, it is productive of vertigo, loss of consciousness and voluntary power, and

not unfrequently of convulsions; apoplexy from congestion, and certain forms of epilepsy passing imperceptibly into each other. When the congestion takes place more gradually as from the effect of narcotics, or habitual indulgence in fermented liquors, or arising in the progress of disease, it is indicated by increasing listlessness, drowsiness, and finally, by coma; temporary numbness, or loss of sensation, or convulsions, being experienced towards the termination of the disease.

The following case is a good illustration of the mingled attack of apoplexy and epilepsy:—

"James Eames, aged 60, was admitted into Guy's Hospital under my care, September 10th, 1829, in a state of great feebleness, with occasional vertigo, from an attack of a mixed apoplectic and epileptic character, which he had experienced a few days previously, and for which he had been cupped; he was a stout-made man, with a bald head and short neck, exsanguine in his appearance, I believe from the frequent necessity of losing blood. I had seen him before, and was no stranger to his history. Six years previously, while he was walking, he was first seized with giddiness, and on the following day experienced a more severe attack, with loss of sight and of consciousness. He was twice bled from the arm, was freely cupped, had cold applications to the head, and gradually recovered, not having suffered during the whole attack any paralysis. Three years and a half afterwards he had a similar seizure, and again about a year after that; subsequently to which he was in the hospital, under the care of Dr. Cholmeley; and while still in the house about a year ago, he had a more severe attack, greatly resembling apoplexy, in which he remained perfectly senseless for several hours, but this was attended with spasmodic action of all the extremities. He was cupped, and recovered pretty speedily, but remained feeble for several weeks; and about six months afterwards had another similar attack. As he was free from the immediate severity of the fit at the time of his being received under my care, I had recourse to gentle purging, and afterwards to tonics, and on one occasion was obliged to cup him at the neck; under this plan of treatment he gained strength rapidly, and left the house in about a month."

In cases of this nature, which are by no means uncommon, the chief point to be decided is, the extent to which depletion ought to be carried, and Dr. Bright observes, that in most instances, in proportion as the epileptic character

preponderates, the propriety of large depletions will become more questionable. Indeed, the abstraction of blood can only be regarded as a temporary means, calculated to remove present danger, which having been effected, keeping up regular action of the bowels, with tonic regimen, is best calculated to guard against relapse.

Next in succession we find a set of instructive cases, shewing the tendency of narcotic poisons to produce congestion in the brain. In the following case, which proved fatal, the state of the cerebral vessels was matter of demonstration:—

Poison by Opium—Great Vascular Congestion of the Brain.

“—Williams, a young woman, was brought to Guy's Hospital January 21st, 1825, in a state of profound coma, from the effects of opium, taken about two hours before her admission, with a view to self-destruction. The quantity she had swallowed was not exactly known. The stomach-pump was freely used, both to wash out the stomach and to administer stimulants; but sensibility never returned, nor did she ever so far recover as to be able to swallow, and she died about fifteen hours after admission.

“ *Sectio Cadaveris.*—Vessels of the head unusually turgid throughout, and on the surface of the anterior part of the left hemisphere of the cerebrum, an ecchymosis was observed of a very light colour, about the size of a crown-piece—such as a very few drops of effused blood might have produced. The bloody points were very numerous in the cut surface of the brain: there was no serum collected in the ventricles. The stomach was quite healthy, except two or three spots of ecchymosis, which were ascribed to the tube of the stomach-pump; there was on the whole less vascularity than usual. In the large intestines were some appearances of inflammatory action. A small ovarian tumor, about the size of an orange, was found in the pelvis.”

But all cases come not to this unhappy end, even where large quantities of laudanum have been swallowed, and Dr. Bright relates three instances in which “an ounce and a half,” “something more than two drachms,” and what was believed “to exceed an ounce,” were taken; their baneful effects being warded off chiefly by the affusion of cold water upon the head, in the manner recommended by Mr. Wray some years ago, in a paper which he published in the Medical Repository.

MEDICAL GAZETTE.

Saturday, October 22, 1831.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”—CICERO.

USE AND ABUSE OF CERTAIN COLLEGE REGULATIONS.

WE have been a good deal amused during the last week or two with witnessing the cool impudence and empty babble of a would-be director of study—an open instigator of cabals among the medical students of the metropolis. Amused we were, because we knew how impotent and harmless were all these unbidden efforts; nay, we should be quite satisfied with the amusement, did we not fear that some unlucky simpleton or other might be misled by the contrivances of the medico-political mountebank. As he “bides his time” with the instinct of an animal of mischief, he calculates about this period on the number of the inexperienced whom he may hope to delude; nor does he scruple to employ the most abject arts of insinuation to gain the ear of those who are about to enter upon their earliest course of medical study. To reason with him, or to reply to the sort of trash which he indites, were out of the question; it would first be necessary to know exactly what he aims at—what it is, in the name of every thing incomprehensible, that the man means to insist on? Is it the abolishing of all rule and government in the profession? or rather, is it not his notion that he may eventually be able to set up some fabric of his own upon the ruins of all that is respectable in our time-honoured establishments? The blockhead! the merest tyro could expose his folly and presumption.

Attending hospitals and lectures, and afterwards receiving certificates—

are not these the chief objects of the man's hostility? Has he not, in his very last effusion, held up the clinical instruction that could be afforded by a private country practitioner as equivalent to that which the student could obtain from our greatest hospitals? Let us have the language itself in which his notable scheme is described. His country-master is surely a most accomplished character:—

“He furnishes his apprentices with *repeated demonstrations in anatomy and botany*, and reads to them during an hour or two daily, upon subjects connected with *the theory and practice of medicine*. With a view of making them acquainted with *pharmaceutical chemistry*, he experimentalizes with his pupils in his *snug little laboratory*; and with a wish to teach them diagnosis and prognosis, he causes *one of his apprentices daily* to accompany him *to the bed-side of the sick*; while, in order to render familiar to them those changes which the various organs of the body undergo from the progress of disease, he neglects no favourable opportunity of instituting *post-mortem examinations* (!) Thus tutored, how can these apprentices fail to acquire a knowledge of their profession?”

The question is really too silly to merit a reply. The personage (of whom more anon) who doles out these copious stores of medical tutorship, is, a little higher up, described as one who had just “walked the hospitals” in this metropolis, who had reluctantly acquired the “requisite quantity of recognized certificates,” had happened to succeed in passing the “ordeal” of an examination for his diploma, and who had but lately “plunged into the active duties of his profession;” when, being “happy to avail himself of the assistance of one or two apprentices,” he succeeds in swindling the parents of the hopeful youths out of 200 or 250 guineas for

each, under the *false pretence* of completing their education for those sums. And this is the able gentleman whose tutorial care should supersede the acquisition of recognized certificates, and the attendance of London hospitals; this the *beau ideal* of the medical millenium which is to take place upon the abolition of the old system! Surely chaos must come again.

Hospitals! who is so weak as to endure for a moment the folly of him who would undervalue them? Hospitals! without which even the best appointed schools (if they can be said to be appointed at all without them) cannot be looked upon as half made up—can scarcely deserve the name of schools so long as the defect exists. We should be paying but a sorry compliment to the understanding of our readers were we to dwell upon the thrice-told tale of the great advantages of hospital attendance in the acquisition of a competent medical education; and we decline the task the more willingly as it has been so recently and so ably done in our pages by the accomplished professor of medicine in the University of London. But we cannot suppress our indignation at the bold effrontery of the man who is not ashamed to stand forth as a public adviser, and to advocate the possibility of their being dispensed with.

And is there a shadow more of feasibility about his notions regarding certificates? Questions may arise, as they have often arisen of late, touching certain differences as to the persons from whom certificates should be received; but we believe there never was a time when those documents were not demanded as a preliminary for an inaugural examination—as a rational, and in some sort a sufficient guarantee, that the individual presenting himself was not unworthy of being admitted to the test—a test which, without it would either have to be conducted with a painful minuteness, or be liable to frequent

frustration, from the circumstances of disreputable persons offering themselves as candidates, and from the growing prevalence of the cramming system.

Time was, undoubtedly, when restrictions had to be imposed upon those who, without sufficient reason, assumed to themselves the right of bestowing certificates; when, in consequence of the great increase of persons educated to the profession, many additional schools were set up—places in which, for temporary purposes, inefficient plans of instruction were adopted—and where persons became teachers who were totally unprovided with the suitable apparatus, preparations, drawings, clinical wards, or subjects for dissection. This grew, at length, into an evil which could no longer be endured.

Nice distinctions had to be adopted with regard to the bodies or individuals to whom this important privilege of giving certificates was to be entrusted; and, from time to time, alterations had to be made, all tending to check the intrusion of unworthy characters, and to maintain the respectability of the profession. But we conscientiously believe, that the privilege is at this time fully as freely and judiciously communicated as it can be, with due protection to the interests of the medical republic; nor shall we take the word of any disturber who would prompt us to demand its more unrestricted bestowal—much less the abolition of the whole system.

The absurdity of the proposal is not a little ingenious. Abolish hospital attendance, and dispense with certificates! Upon what ground? Who proposes it? Why, one who has no connexion whatever with hospitals, because hospitals will have no connexion with him—and who has had no interest in the “certificate system,” because *heretofore* he has never had a certificate to bestow; but one who has now a nostrum of his own to recommend, which

is to cure all the diseases incident to medical education. Oh! the disinterestedness of this noble-minded projector—who has no other object than the establishing of a poor “cave of Adullam,” a REFUGE FOR THE DESTITUTE, whether all who have nothing to lose, but every thing to gain, and are discontented with their present condition—particularly broken-down teachers of anatomy—may betake themselves, with the hope of comfort from the “eleemosynary fund!” Why should hospital tickets be purchased, or certificates of any sort obtained, when the price of the very cheapest of them were enough to buy a place in the “refuge?” And a place in the refuge makes a man a Doctor at once, and entitles him to the privilege of the fund. These must be allowed to be “advantages seldom offered to the public, and never equalled;” they are, moreover, seldom likely to be offered again—so now is the time to secure a bargain.

But what constitutes the most striking feature of the new establishment is, that it offers, like the cave of the Israelite, a most desirable haven to “every one that is in distress, and every one that is in debt;” and, we suppose, to every one that has got himself into the meshes of the law for the “good cause’s” sake. And this, by the way, reminds us of a letter which we have just received, bearing on the subject in hand: we shall make no apology, but give it to the reader at full length.

To the Editor of the London Medical Gazette.

Taunton, Oct. 18, 1831.

Sir,—I must appeal to your generosity for setting me right before the public about a little matter in which I am concerned here, and an account of which I sent the *Lancet* last week; but what was my astonishment at finding my private and confidential communication laid before the readers of that journal in a garbled and strangely altered form!

I applied for advice in a bit of a law difficulty to the editor of the *Lancet*—knowing how clever he is in scrapes of this kind—but I did not want to have myself exposed, nor my name given to the public: judge, then, of my surprise and annoyance, at finding myself betrayed—I say *betrayed*—by the awkward management of that gentleman. Sir, my name is Cureall, or more properly Cur'l, as it is still pronounced here, and I live in this town, having a decent practice of from two to three hundred a year. There is no reason now why I should conceal any thing from you: I am exposed and disgraced—myself and my business, by the way in which I have been introduced into the pages of your contemporary: I am regularly blown up by having any thing to do with that magazine of scandal and absurdity; and I have no hope of recovery but by throwing myself on the public generosity through your kind interference.*

You must know then, sir, that I am lineally descended from the celebrated Edmund Cur'l, of whom such honourable mention is made in Pope's works: this should be some guarantee for my claim to a character for learning. The name by some corruption, I suppose from the connexion of some of my later ancestors with the healing art, has descended to me as Cureall; and by that denomination many of your readers will, perhaps, recollect my father, who was sentenced to confinement in Ilchester jail for twelve months, for having been unsuccessful in an experiment with prussic acid, which he tried in the cause of science. From him I received the first rudiments of my general and medical education; and, in process of time, came to London, where, to do your contemporary justice, I found the hospitals the most useless places I ever stepped into. I learned nothing; I walked them—that was all. None of the surgeons seemed to care any more for me than if they never saw me, or had never received my money. It was the same way at lectures. I attended all the prescribed courses at one of the great hospital schools, and, except when paying for my tickets, never had the honour of enjoying the conversation of any of my preceptors, who in fact spoke only to those who were anxious for further information, and I did not need that. I would have been quite solitary, and perhaps have died of the va-

pours, had I not picked up with some despised pupils like myself, and with them contrived to spend the time pretty tolerably until the courses expired. Well, for all that, I was not deficient at the examination. I was always ready at gathering knowledge, and contrived to have enough to secure my diploma. What with the talk which I could always muster, on no matter what subject, and what with a little *cramming*, I passed. But what does it signify how I passed, when I am conscious that I know quite enough for any country practitioner? I was not going to be an hospital surgeon, or a metropolitan teacher; and so, in short, with that impression, I went home and began to practise.

It is not true that I bought a business; no, I got into notice by the credit I had of being all-accomplished, coming straight from the feet of the Gamaliels in London; not that I have got into any such mighty practice either, but my London education, and my easy account of it, stood my friend and got me a couple of apprentices, with whom I secured very respectable fees. Of course I said nothing, when taking the lads, about regulations of hospital attendance, and certificates from recognized schools. I always thought, with your contemporary, that they were odious and disgusting things; and, having equity on my side, I set my conscience at rest. The parents of my apprentices, I knew, would hear of these odious regulations some time or other, and would be readily convinced of their grossness; and, besides, they were very well able to bear the loss, or to go to law with the College, if they thought fit. I thought, too, that if they did, it would be no harm; and I should have the credit of being instrumental in effecting this most desirable consummation. I merely promised to make surgeons of them; and surgeons they are, I have no hesitation in saying, as good as myself. I taught them, it is true, more theory than practice—that was unavoidable; but I taught them the most useful practice: what is the use of capital operations I would be glad to know? I never had a capital operation to perform in my life, and perhaps never shall, but I have had a fair share of the useful minor surgery—much teeth extraction, phlebotomy, treatment of cut shins, sprains, and burns; and what more does a country practitioner

require? "My snug little laboratory"—oh come, that is too good a joke! I may have mixed sulphuric acid with infusion of roses, or lemon juice with solution of soda, but as to direct experiments for learning or teaching chemistry, that is all—nonsense. Clinical instruction I certainly gave when I could, and I remember we once had a fine fever case for a post-mortem; but I never could venture upon a *subject*; I should have been taken up for a resurrection-man, I have no doubt, if I attempted it, and I always had a wholesome fear of the law of misdemeanors before my eyes.

Well, now came the time for it. My pupils' apprenticeships expired, and they were to be examined in London without more ado. I gave them their indentures, and a general certificate for what I had taught them, and desired them to demand an early examination at the College. With what anxiety did I await the first post after their arrival: it all came out at once: a knock at my door; the fathers of my pupils enter to insist upon an explanation of their sons' being refused examination. I explained the gross injustice of such an occurrence, and proved how they *could* not be refused. "But, zounds! sir, they *have* been refused," cried one of my furious visitors. It was of no use: they swore they would not be trifled with; and, sure enough, it was not long till I had notice of an action for *swindling* served upon me, and that action now pends.

Now, sir, I appeal to you, is not this a scandalous result of the London Hospital and Lecture-certificate system? Am I not a martyr to the "horrible and disgusting," "cold, unfeeling, and relentless" system pursued by the College? But, as I said before, I throw myself on your generosity, and leave my case entirely in your hands; though, to tell you the truth, I should not have troubled you, had not Wakley made so base a use of my confidence.

Your most obedient, humble servant,
PETER CUREALL, M.R.C.S.

However much we may be obliged to Mr. Cureall for the honour of his transferred confidence, we fear he will not find us of much use to him: we would recommend him though, by all means, to become reconciled to his old

patron and adviser as soon as possible, and perhaps he may thus be enabled to exchange his "snug little laboratory" for a snug little professorship in the Refuge for the Destitute. In the meantime, the best thing we can do for him, we have done: *littera scripta manet*: what he has written, he has written; and his epistle carries its own commentary along with it.

FACTS REGARDING CHOLERA.

GREAT pains have been taken by Drs. Russel and Barry in tracing the history of cholera as it manifested itself at St. Petersburg and the adjacent places. Their inquiries have been chiefly directed to ascertaining its mode of propagation, with a view to determining the question of contagion; and although some of the facts are difficult to reconcile with any of our prevalent theories upon the subject, yet we must say that the great majority of them point to infection conveyed by persons, and not by goods or clothes, as the usual source of the contamination. The gentlemen alluded to seem to have exerted themselves to lay aside all preconceived opinions—marking the events passing under their own immediate observation, and in tracing the history of what they did not themselves witness—admitting only the testimony of those who had seen what they narrated; a caution which they were led to adopt in consequence of the colouring which they found to be often given to circumstances according to the views entertained by the narrator as to the nature of the disease itself. Of the many important facts which their last letters (received a few days ago) contain, we can only give a few, but we hope soon to see the whole laid before the public in a systematic shape. There is at St. Petersburg a city prison, under the medical charge of Dr. Bish, an intelligent physician, and

previously to the appearance of the epidemic, an anti-contagionist. He, as well as all the other officers of the establishment, resides within the walls of the prison, by which all communication with the neighbourhood is prevented. On cholera appearing at St. Petersburg, all intercourse between the gaol and the town was rigidly cut off, and no instance of the malady occurred for some time; but at length the wife of one of the prisoners, she being also a prisoner, was readmitted from one of the hospitals to which she had been sent to be cured of a syphilitic complaint, no one labouring under such being retained for treatment in the prison. On her return she passed through the apartment where her husband was: she spoke to, and saluted him, but proceeded in a moment to the part of the building appropriated to females. She had some diarrhœa when admitted, which on the following night proved to be cholera, and of which she died in twelve hours. Three women, who had been in the room with her, were next taken ill, and after them her husband, who also died. There were four hundred persons within the walls, and of these twenty-seven had cholera, which in fifteen proved fatal. No case occurred in the portion of the prison allotted to nobles, it being apart from the rest.

There is a German colony on the Neva, thirteen versts from St. Petersburg. The houses are detached with gardens, and the surrounding country highly cultivated, while the inhabitants are more cleanly, and fonder of the open air, than the Russians. Thither some persons fled on cholera appearing in the capital; one of these, a female, took the disease, and died of it; but it did not spread, no other instance of it having occurred, though her bed seems afterwards to have been used. Indeed, there are many instances in which the beds and clothes of those who have died, seem to have been made use of with im-

punity. Opposite this colony, on the other bank of the river, which is there about the breadth of the Thames at Blackfriars, are Russian villages; but they did not escape, though the locality was as salubrious as that of their German neighbours. It is a curious fact, that another German colony, on the road to Moscow, between Yshora and Colpina, escaped, although the disease raged at both the places just mentioned; but it was observed that no travellers ever stopped at the German village, because the others afforded much better accommodation.

At Cronstadt, as at Moscow, no case occurred among the military cadets (150 in number), all communication having been cut off between them and the rest of the fortress; but, on the other hand, several instances happened where persons had the disease, though no communication with any source of infection could be traced. Thus a man, confined by hæmoptisis on the third floor of a house, who had not been out of the room for many days, and who saw no one who had been exposed to the disease, took it notwithstanding. At the Foundling Hospital a good many children died of cholera, and several nurses had it; and it is a curious fact, that when any of these last, who were suckling, had the disease, so as to render it necessary for the infant to be given to another nurse, none of those who gave the breast in this way became affected with cholera, although, in many instances, the infant's clothes were not changed.

QUARANTINE.

WE understand that most vigorous arrangements have been made for the purpose of excluding cholera from our shores, if this is to be effected by quarantine. We hear that a considerable additional number of ships of war have, within the last week, been ordered upon this service.

DRS. RUSSEL AND BARRY.

THE Russian Government has conferred the decoration of St. Anne, of the second order, on Drs. Russel and Barry, for their zealous and scientific investigations on the subject of cholera at St. Petersburg. These gentlemen are supposed to be now at Hamburg, where the presence of the cholera will probably detain them for some time.

THE CHOLERA AT VIENNA.

THE mortality from the cholera in this capital, during the first month of its visitation—that is say, from the 13th of August to the 13th of September, amounted to no more than one hundred deaths. But about the latter period, a heavy rain and storm having prevailed for the better part of three days, the disease broke out with the most alarming violence on the night of the 13th, and, in the course of four-and-twenty hours, swept away eighty victims; and this principally in the *city*. In one little street, not containing above ten or a dozen houses, six persons died on that night. The higher classes seem to have been peculiarly singled out for the ravage; and the Doctors Sidprowitsch, Gassner, and Roehrig, were among the first who fell. Since this alarming burst, however, the cholera has not gone on with proportional fury: it is comparatively tranquil, though the deaths are still by no means inconsiderable.

If the local peculiarities of Vienna be taken into account, it is not difficult to explain why the higher orders have particularly felt the severity of the disease, and also why the *city* has been its principal hamlet. Vienna, the city, is small, compact, and surrounded by suburbs, from which it is separated by a wide glacis. The streets are very narrow, and the houses immoderately

high. Yet it is here that the higher classes reside, though their first-floors are generally destitute of both air and light. The lower classes, meantime, enjoy the upper stories, as well as the more spacious and airy suburbs.

It should not escape observation, too, that Vienna is almost completely hemmed in with a chain of mountains; which, however, do not protect it from violent gales during the best part of the year, and especially about the equinoxes.

Rheumatism, in a severe form, is a constant resident at Vienna; and, every autumn, a malignant dysentery prevails, of which the mortality is considerable. The people, too, it may be remarked, particularly the higher orders, are fond of *good living*.

On the whole, it would seem to augur well for the future progress of the complaint, that in Vienna it has not been more severe; for few cities in Europe, perhaps, possess more of those elements which constitute the *fomites* of this direful malady.

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

REPLACEMENT OF NOSES.

DR. BARTHELEMY, in a paper in the *Journal Hebdomadaire*, on the re-union of parts entirely separated from the body, gives the following nose cases, which he says he has had upon the best authority. The first of them he obtained from a lady, who gave him *her honour* that it was true. A soldier, at Lyons, in 1815, had the end of his nose cut off in a duel by his adversary's sabre. He put the piece of nose in his pocket to keep it warm, and returned home to his lodgings. A surgeon was sent for, who put the disunited parts together again; and they *took* to admiration.

For the following case the veracity of Dr. Regnault, of the Military Hospital of Grand Caillon, is pledged. In the prison of Niort two men had a fight, in which one of them bit off a considerable portion of the other's nose. The unfortunate fellow who suffered the mutilation did nothing for four or five hours but deplore his loss: the piece of nose, however, he picked up, wrapped it in his handkerchief, and put it in his pocket. A fellow-prisoner suggested to him the propriety of applying to the surgeon of the jail, to see what he could do for him; he did so, and the medical officers having speedily warmed some alcohol, steeped the part in it, and then put the divided surfaces together. At the end of ten days they were solidly united.

ACTION OF VARIOUS MEDICINES ON THE HEALTHY BODY.

A set. of experiments has recently been performed at Leipsig on the action of several important medicines on the healthy body. They were made on twenty-two physicians and medical students, between the ages of twenty-one and forty-five; two boys, and three females, one twelve, another eighteen, and the third forty-five years of age.

Nitrate of Potass.—Eight members of the association above mentioned took twice a-day doses of nitre, gradually increased from fifteen grains to a drachm, and the effect was excitement of the kidneys, intestinal canal, and skin. The sensation of coolness felt in the mouth, throat, and sometimes the stomach, on taking a solution of nitre, is soon followed by a state of re-action, accompanied by increase of the pulse. It is, therefore, not an antiphlogistic, as some physicians imagine. It ought to be prohibited in all inflammatory affections of the alimentary canal or genito-urinary system; neither is it a proper remedy in cutaneous diseases, except to produce determination to the kidneys or intestines. As a purgative it ought to be altogether abandoned, since we possess many safer and more certain medicines of this class. As a diuretic it may be admissible in some acute dropsies, but in general it is an ineligible diuretic, for other remedies of the same class are more powerful and safe, and do not disorder digestion, as nitre does, when long

continued. The best effects are to be procured in inflammation of the brain or its membranes, or of the throat, or even of the chest. According to the experiments made with it on the females of the club, it is an emmenagogue.

Cherry-laurel water.—The article made use of was prepared by distilling three pounds of liquid from a mixture of six pounds of water, one ounce of rectified alcohol, and one pound of fresh laurel leaves chopped. Twelve members of the club took it in doses progressively increased from five to twenty-five, and finally to one hundred and twelve drops. Its whole action appeared to be concentrated on the brain, the symptoms being a sense of weight in the head, sleepiness, torpor of the intellectual functions, general lassitude and feebleness, retardation of the pulse, corresponding in degree to the headache; and this state was preceded by dull and pungent pain in the head, chiefly in the fore part, in the region of the optic nerves. The pathological cause of all these symptoms appeared to Professor Jörg to be turgescence or plethora of the blood-vessels of the head. It likewise produced unpleasant tickling in the larynx, cough, and an increased secretion of mucus, continuing sometimes for several days, and constituting a slight attack of bronchitis. Hence he infers, that cherry-laurel water is contra-indicated in inflammation of the brain and lungs, and in the first stage of scarlatina and puerperal fever. By its secondary action in lessening nervous sensibility and retarding the circulation, it may be useful in inflammation of the abdominal viscera, or organs of generation, or in excitement of these organs without inflammation. It is contra-indicated, he further conceives, in spasmodic affections where the cause is excitement of the brain, or turgescence of its vessels. M. Jörg has found that the cherry-laurel water, like the other forms of prussic acid, is rapidly decomposed, and likewise that its effects on different people are very different in degree. Bitter-almond water, though stronger in taste and odour than cherry-laurel water, is less active and more uncertain in its physiological effects. The effects of pure prussic acid are similar to those of the cherry-laurel water.

Valerian.—This was taken in infusion in the dose of from two to eight

drachms in four ounces of water, or in powder in the dose of half a drachm or a whole drachm, or in the form of tincture in various doses. Sometimes no effect was manifested; sometimes it acted on the brain; sometimes on the alimentary canal. When the brain was acted on, excitement was first remarked, being indicated by serenity or disposition to liveliness; then slight congestion followed, as was shewn by the sense of weight in the head; but there was never prostration nor torpor, as after other medicines which have the same kind of action. When the alimentary canal was acted on, eructations were produced, with a sense of fullness in the stomach, flatulence, colic, and tenesmus; sometimes nausea, with a bitter taste. Valerian likewise quickens the circulation, though moderately. It was farther remarked that the action of half a drachm continued four hours, that of two drachms twelve hours, that the action on the stomach is most easily induced by the powder, that on the brain by the infusion, and that the disagreeable taste of the infusion passed away quickly, while that of the powder remained several hours. M. Jörg concludes from his experiments, that valerian may be useful in supporting the strength whenever inflammation is not present; but that it is contra-indicated whenever there is congestion in the head or abdominal viscera.

Serpentary.—Ten members of the club tried the effects of serpentary in the dose of from two to five scruples infused in four or eight ounces of water, and likewise in the form of powder in the dose of fifteen grains or one scruple. The result was that it excited the intestinal canal, produced determination to all the abdominal viscera, and occasioned flatulence. The usual symptoms were eructations, nausea, vomiting, pain in the stomach, colic, discharge of wind downwards, tenesmus. Sometimes, too, it produced a sense of heat, weight, and pain in the head, and at other times excitement of the circulation, or increased urinary secretion. Its effects lasted from eight hours with small doses, to twenty hours with large doses. It is therefore inferred to be a remedy which can only be useful when the practitioner wishes to rouse the vitality of the alimentary canal; hence in particular it may be useful in colliquative diarrhoea,

not connected with inflammation, as it tends to diminish the secretion of mucus.

Arnica.—*The Flower*, in the dose of from two to thirty-six grains infused in from one drachm to six ounces of water, was taken by thirteen individuals. It produced much irritation in the whole alimentary canal from the mouth to the anus, particularly in the gullet, stomach, and small intestines, exciting rather increased contraction in these parts than increased secretion. It likewise excited the brain, probably through sympathy with the intestines; and a distinct acceleration of the pulse, increased perspiration, and various modifications of the urine were also observed among its secondary effects. Its action lasted from twenty-four to thirty-six hours. The conclusions are, that the flower of the arnica may be useful in general or local debility of the intestines, brain, or locomotive organs, but is contra-indicated when there exists irritation or inflammation of the intestines, or congestion in the brain. Externally, an infusion in eight parts of water caused heat and itchiness of the skin without redness; and the flowers themselves also produced redness in eight hours, without affecting the cuticle. Thus they appear to be useful rubefacients of the mildest kind. *The Root* affects the muscular coat of the alimentary canal and the brain, more powerfully than the flowers; and hence M. Jörg thinks it may be useful in chronic or colliquative diarrhoea, without inflammation, where the object is to strengthen the intestinal canal without augmenting its mucous secretion. Besides these effects, both the flower and root appeared to have a powerful effect in stimulating the absorbent vessels, and may be useful, as they have been conceived by some to be, in promoting the removal of indurations of various organs. In this respect they have some analogy to calomel in action; but they have a greater tendency to excite inflammation.

Camphor was sometimes taken in powder in the dose of half a grain, and from that to twelve grains—sometimes in the form of tincture in the dose of half a grain, and from that to four grains. The result was, that it stimulated directly the brain and alimentary canal, and indirectly the urinary organs, the skin, and organs of circulation. The effects on the brain were very different

in degree on the different individuals—some experiencing much excitement, and being then thrown into profound sleep, while others remained free from any cerebral disturbance. It increased the heat of the body in all, and often produced sweating; it accelerated and strengthened the pulse, modified the quantity and composition of the urine, and excited the organs of generation. Camphor would thus appear to be contra-indicated in acute inflammatory fevers, and in irritation of the urinary organs, however contrary this principle may be to the usual therapeutic creed of physicians, and in every state of the cerebral system where congestion either exists or is apprehended. It is indicated in diseases of debility, and as it does not produce visceral congestion in the abdomen like the two preceding, it should be used in preference to them in tympanitis and colliquative diarrhoea, not connected with inflammation. The dose should be half a grain to one grain or upwards.

Castor in the dose of ℥ss. produced in all who tried it disagreeable eructations, but no perceptible effect on any system of organs, and in small doses it had no effect of any kind. M. Jörg therefore concludes that it might be erased without detriment from the list of the *materia medica*.

Musk was taken by nine persons in doses varying from two to fifteen grains. It appeared by no means so diffusible a stimulant as is generally supposed. It powerfully excited the alimentary canal and the brain, producing eructations, sense of weight in the stomach, and dryness in the throat; also sense of weight in the head, and giddiness. The secondary effects on the brain were more prominent; the symptoms consisting of yawning, somnolency, depression, and finally deep, prolonged sleep. When the dose was large, trembling and even slight convulsions of the limbs occurred. It excited the circulation, rendering the pulse fuller and more frequent. It never produced its peculiar odour in the sweat, urine, or other secretions. His experiments led the writer to infer, that musk can only be used in debility of the brain and nervous system, when no congestion is present—but that it is not so appropriate a remedy in extreme nervous debility as is commonly supposed, since the stimulus it produces is followed by a cor-

responding collapse. Three or five grains are a sufficient dose; the effects cease in eight or twelve hours.

St. Ignatius Bean.—From half a grain to four grains of the powder, or from nine to ninety drops of a tincture made with eight ounces of alcohol and one ounce of the bruised seeds, produced salivation, nausea, weight and pain at the epigastrium, eructations, colic, constipation, or purging, and irritation of the anus. Its secondary effects were weight in the head, giddiness, pain and inflammation of the eyes, and finally much prostration and apathy, sometimes with increase of pulse, and a sense of creeping and pricking in the urethra. These effects disappeared and reappeared several times. Professor Jörg recommends it in weakness of the stomach and intestines, especially when attended with induration of the mesenteric glands; in diseases of a periodic character, as a powerful alterative; and in atony of the brain and weakness of sight. The dose should be half a grain of the powder once a-day; it may be gradually increased.

Assafoetida.—This, in doses varying from one to fifteen grains, stimulated the alimentary canal, particularly the gullet, stomach, and small intestines. Secondly it produced cerebral congestion, indicated by dull pain and excitement of the circulation and respiration. It also produced strong excitement of the genito-urinary organs. Hence its use in indolence of the digestive organs he considers well-founded; but he is inclined to doubt the propriety of its almost universal use in hysteria and hypochondriasis, when depending on irritation of the uterine or abdominal organs. He thinks it is usually given in too large doses, and too often; from half a grain to one grain he generally found sufficient, and the effects often lasted till the second or third day.

Digitalis, in doses varying from half a grain to three grains, excited directly and powerfully the brain, the alimentary canal, and the genito-urinary organs. Its secondary effects were directed on the circulation, which it depressed. Its operation on the brain was indicated by intoxication, giddiness, dull headache, warmth of the face and dimness of sight; its operation on the alimentary canal by a sense of heat in the pharynx and gullet, colicky pains, and sometimes increase, sometimes diminution, of appe-

tite and of the alvine discharges; its operation on the urinary organs was evidenced by a remarkable increase in the secretion of urine, observed in all but one, and attended sometimes by diminution, sometimes by increase of its colour; its operation on the genital organs by itching of the glans, and by erections, and in females by symptoms resembling those which precede menstruation. The consecutive effects were marked depression of the circulation, indicated by feebleness and smallness of the pulse; which, however, were always preceded by excitement.—From these results, the author concludes that digitalis is far from being an appropriate antiphlogistic remedy;—that it is contra-indicated in hooping-cough, acute hydrocephalus, and all dropsies connected with inflammation of the serous membranes—the very diseases, in fact, in which it is chiefly used; but that it is very useful whenever the object is to stimulate the urinary organs to increased secretion. He questions the propriety of its employment in diseases of the heart, as its depressing operation must prove hurtful in some and useless in others. The dose should be from a quarter of a grain to a grain of the powder, and when its action has commenced the dose should not be repeated oftener than once every twelve, twenty-four, or forty-eight hours, as its effects often continue thus long. In unnecessarily large doses he is inclined to think it may tend to induce an inflammatory state of the urinary organs, and consequently diminution, instead of increase of the secretion of urine.—*Archives Générales de Médecine*.

CAMPHORATED OIL IN CHOLERA.

In lieu of cajeput, when dear and scarce, M. Champonnier, of Paris, recommends the medicinal use of a compound of olive oil and camphor. The proportion is twelve grains of camphor to the ounce of oil. The dose is a teaspoonful, in a warm drink, taken every hour if the symptoms are urgent, every second hour if not so severe. Tea, he thinks, is the best menstruum. The natives of India employ for the same purpose, and with good success, a warm infusion of the leaves of the *laurus camphora*, in sweet oil. M. Champonnier's design is to imitate them, and he adds, that he has found his compound a most valuable remedy, and a complete substitute for cajeput.

DIAGNOSIS OF HYDROCELE.

A very simple and ingenious method of ascertaining the transparency of the parts in obscure cases of hydrocele, has been hit upon by M. Segalas, and submitted to the Académie de Médecine. He merely applies to the scrotum one end of the eye-tube which is employed for exploring the urethra, and puts his eye to the other, upon which the existence of fluid, if it be there, becomes manifest. The result is explained by the isolated condition of the eye, the perpendicularity of the rays of light transmitted through the tube, and the pressure of the instrument against the scrotum. M. Roux, however, doubts the utility of this method in certain cases; for instance, where there is a cartilaginous thickening of the tunica vaginalis; and upon the occasion of discussing M. Segalas' contrivance before the Académie, the professor mentioned the curious fact of the extreme transparency of the scrotum in some examples of sarcocele. He was lately called in to a case of this kind, where the surgeon in attendance mistook the complaint for a simple hydrocele, misled by the transparency of the parts, and neglecting to take into account the specific gravity.—*Gazette des Hôpitaux*.

[M. Roux's objection, in the meantime, proves nothing; and perhaps the only circumstance that would tend to depreciate the utility of the new method, is, that it enables us to see *too well*—to discover transparency where such a thing would be least expected. With the tube and a candle light may be perceived through the palm of the hand.]

CLINICAL LECTURES,

Delivered in the Dispensary of the London University,

BY

DR. ANTHONY TODD THOMSON.

LECTURE I.

October 12th, 1831.

General Observations on Clinical Instruction.

GENTLEMEN,—In commencing the series of discourses which I propose to deliver, on the nature and treatment of the diseases which are brought under your notice in this institution, a few remarks on their utility may not be unimportant. Such discourses

are generally called *clinical lectures*; but, in the strict signification of the term, no discourses can be termed clinical except those which are delivered at the bed-side of the patient, and which have a reference to the immediate state of the disease which is there under the eye of the student. Were it admissible, in any situation, or under any circumstances, to disregard the feelings and to overlook the safety of the patient, for the benefit of the student, such a plan of instruction would be highly advantageous; but this is a sacrifice which humanity and justice equally forbid; and, therefore, the discourses to which the term clinical is applied, refer merely to cases actually existing, which have been recently seen by the student. Their intention is to explain the practice that has been adopted, and to make evident to the pupil the principles by which the practitioner treating them has been guided: in plain language, to display to the student the mode of applying and rendering practically useful the instructions which he is supposed to have previously acquired, in the various elementary branches of medical science, from attendance on lectures. Such is the nature of the instruction which you are to receive from me in this place: the real object of it is to make you acquainted with the phenomena of disease, and the effects of medicinal agents in counteracting these, or in restoring the healthy state of the system.

It has been supposed that dispensaries are little calculated to afford much information respecting diseases, from the absence of proper opportunities for tracing correctly the influence of medicines; and that it is in hospitals only, where the patients are completely under the control of the physician or the surgeon, that these objects can be fully attained. Far be it from me, gentlemen, to depreciate the utility of these institutions, which shelter, whilst they administer to the relief of the poor and friendless, whom disease has overpowered, or whom accident has rendered incapable of pursuing their ordinary avocations: they are the noblest monuments which can be erected to the glory of a nation, to those godlike feelings of benevolence and charity, which are the boast of England; and, assuredly, in no part of the world are their duties more ably or more humanely fulfilled. But to assert that it is in these institutions only that practical medicine can be taught, is assuming too much; for, although we must admit that, when the patient is completely under the control of the physician, the progress of disease can be most correctly and closely observed, symptoms traced to their sources, and the real influence of remedies ascertained, yet, it must be borne in mind, that this is not the state in which the practitioner is to combat diseases in private practice.

Under such circumstances, therefore, the treatment of every case must be regarded simply as an experiment, successful or otherwise, which teaches the practice of medicine, when the patient is placed in a situation the most favourable for the fulfilment of the various indications contemplated by the physician. If you suppose, gentlemen, that the results which you witness in the hospital are to follow the administration of the same medicines prescribed for similar disease in private practice, you will soon find yourselves woefully mistaken. It is not disease only that you have then to combat: injurious localities, occupations, unwholesome food, extremes of temperature, habits, passions, prejudices, all array themselves against your judicious efforts, and the best directed skill, and too frequently render it difficult to decide, how much of the benefit following any line of treatment is to be conceded to nature, how much to be attributed to art. If these remarks be correct, it is not too presumptuous to assert, that whilst hospitals are essential in the education of a physician—under which term I comprehend every well-educated practitioner of medicine—in order to teach him the nature of diseases and the value of remedies, dispensaries are equally so, inasmuch as they display to the student the effects of the treatment of diseases, under those circumstances which are likely to influence his practice, and to modify powerfully the operation of medicines, in every step of his future career. In these institutions, he sees the patients in the situations which they occupy in society—surrounded by all the inconveniences which attend poverty—borne down by vexations and anxieties—and, because free from the restraints imposed in an hospital, perhaps still under the sway of obnoxious habits, from the indulgence of which their diseases may, in a great measure, have originated. To observe the influence of medicines on disease, under such circumstances, is of the utmost importance to the student: he acquires an additional art, invaluable in the practice of his profession,—that of overcoming the obstacles to the accomplishment of his object, which seldom or never present themselves in hospitals. The hospital physician resembles a pilot who steers his vessel into a safe harbour, amidst the shoals and hidden rocks which obstruct its entrance, with the position of each of which he is well acquainted; but who performs his duty in a calm, and under the most favourable aspect of the heavens; the dispensary physician, and the private practitioner, is the pilot performing the same duty amidst the violence of the hurricane; he has not only to look out for the breakers, but to baffle the conflict of the elements.

In making these remarks, gentlemen, it is far from my intention to lessen, in the

smallest degree, the high appraisement which is usually bestowed upon hospital practice: the advantages to be derived by the student who witnesses it with the attention which it merits, are great and manifold: in no other place so well as an hospital can he attain an accurate knowledge of the advantages which remedial agents are capable of conferring; under no other circumstances, I would almost venture to aver, can he witness diseases unmasked and in their true characters; and, undeniably, in no other situation has he so favourable an opportunity of tracing their effects upon organization, and the changes produced by them on the tissues of the body. He not only enjoys the advantage of seeing much, but of investigating deeply; not only the benefit of having pointed out to him the complexities of disease, but also the probability of beholding them unravelled. To deny the utility of such establishments to the pupil would be folly; but, because hospitals hold forth such advantages, are we to refuse to Dispensaries those which they also are capable of affording? I am most anxious, indeed, to clear from your minds, gentlemen, the prejudices which have been so assiduously attempted to be impressed upon the student against the utility of Dispensary practice, by some hospital physicians and surgeons. Believe me, that, although it cannot be regarded as equivalent to that of an hospital, yet, to those who are disposed to observe attentively and to reflect on what they see—to reason, with the aid of their teachers, upon the phenomena of diseases, and to labour unremittingly in attempting to trace them to their causes; it holds out many advantages, not the least of which is the opportunity that it affords of studying exceptions to general rules, and, as I have already said, of anticipating those obstacles to success in the treatment of diseases which will invariably be encountered by them in every stage of their professional progress. You must perceive, therefore, gentlemen, that if the desire of acquiring a practical acquaintance with the phenomena of diseases, and of studying attentively the varied resources of medicine, be sincere, a Dispensary affords many opportunities of doing so; and of throwing, if not a strong, at least an indubitable light, upon the path of the student. Let me now endeavour to point out to you the manner in which these advantages are likely to be secured.

In the first place, be assured, that whatever may be your genius for observation, it will avail you little in the investigation of diseases if it be not based upon the foundation of an intimate knowledge with the elements of medicine—with anatomy, physiology, chemistry, materia medica, and those other branches of science which are justly regarded as valuable accessories in a medi-

cal education. Without the aid of these, indeed, it is possible that an individual of great natural acuteness, and possessing a talent for observation, may attain to considerable expertness in discovering and managing diseases, within the beaten track of practice; but the moment any thing extraordinary occurs, the uneducated practitioner, like the fair-weather pilot, loses his control, and is at once confounded with the vulgar. I must therefore presume, gentlemen, that you are at least somewhat advanced in these studies before you enter as pupils of this Institution.

The diseases which present themselves to the attention of the student in a Dispensary, consequently those which you are likely to see in this place, are seldom of that acute description which requires the daily, I may almost say the hourly, attendance of the physician: but, if they are not those of the most formidable kind, they are those of most ordinary occurrence, and therefore they require to be well understood and readily recognized. The talent for observation in medicine, as in general matters, is strengthened by habit; but it must first be acquired; and the acquisition is not to be accomplished without the closest and most attentive examination, not only of those symptoms which obviously present themselves to the senses, but of those which lie deeper. "He who is incapable," says Zimmerman, "of observing the moral man, will never be able to know diseases." To accomplish this, however, the observations must not be made in a cursory and partial manner; it is not sufficient for the pupil merely to listen to the examination of the physician; he must employ his own eyes and exercise his own reasoning faculties; if he do not fully comprehend the aim of any query in the examination of a patient, he must not rest satisfied until it be explained; and in affording this satisfaction, I trust, gentlemen, you will never find me backward. In the same manner, I am desirous of seeing you inquisitive with respect to the object and the intention of remedies; and believe me, that the more closely you examine their nature and effects, the more confidence you will repose in those that you employ hereafter, and the more you will have reason to hope from their administration.

One of the most important qualifications of a good practitioner, and, consequently, one of those which ought to be most assiduously cultivated by the student, is such a love of sincerity as will lead to the observation of symptoms such as they present themselves, not such as we would suppose them to be. It is by accuracy in observing effects that we gradually acquire the knowledge of causes; and it is by reasoning upon these that we are led to the indications and the means of cure. In recognizing any disease,

therefore, the description of which you may have previously read in books, or to the history of which you have listened in lectures, note down every exception presented by this individual case to the general appearance and progress of the symptoms, as detailed in the general history of the disease; for, as you will discover that all cases offer some exceptions to the general rule, you will find these particular histories of the greatest utility in your future practice.

Students are apt to fall into the common error, that the greatest sum of information is to be obtained where the greatest number of patients congregate; but crowded hospitals, or very well frequented dispensaries, rather embarrass the student than contribute to his instruction. He sees too much, and reflects too little; the rapid succession of objects does not permit him to fix his attention on any of them; in his endeavour to embrace the whole, he receives only an obscure impression of each; and, consequently, can neither understand nor retain the remembrance of those minute circumstances which have regulated the practice adopted; for "the understanding," as it has been justly remarked, "does not gallop so fast as the physician." It is these truths, gentlemen, which have decided me to confine my remarks, in the series of discourses which I am about to deliver to you, to some only of the cases which shall come before us, and to enter rather minutely into the history and the peculiarities of these, than to attempt a large field of research, or to indulge in discursive observation. The advantages of such a selection is acknowledged in the best clinical hospitals, both in this country and on the continent. In the Infirmary of Edinburgh, which contains nearly two hundred beds, the clinical wards to which the observation of the students is chiefly confined, usually contain only sixteen or eighteen patients; and more advantage is derived by carefully attending to this selection, than by daily walking, as it is emphatically termed, the largest hospitals of this metropolis. It is not the cursory observation of a great number of patients, but the attentive consideration of particular cases, which contributes to form the well-qualified practitioner.

Let me warn you also, gentlemen, against committing another mistake too frequent with the young aspirant to practice—I mean that of disregarding the most common phenomena of diseases, merely because they are common and obvious. It is from these chiefly that the student learns to generalize, and to establish his principles. Every disease consists of a series of symptoms following in a certain order. Extraordinary symptoms may occur, and ought, undoubtedly, not to be overlooked; but it is only by a previous and correct acquaintance with the common phenomena, that the deviations from them

can be recognized, and the knowledge of them become practically useful. Every symptom in the concatenation of phenomena is of value in reasoning upon the disease; and the loss of the smallest link in the chain may disable us from pursuing the mazes of the obscure labyrinth in which the origin of malady is too frequently involved. It is only by such a scrupulous examination of the circumstances characterizing diseases that they can be familiarly recognized—that effects can be separated from causes—and that the influence of remedies can be accurately noted. The disease ought to be as readily determined as the face of a well-known friend; and when the examination is once fully accomplished, the information acquired is not confined to the occasion which called it forth, but is extended to the whole life of the physician. It is this which constitutes experience; and a close attention to which distinguishes one practitioner from another. But in noting, carefully, the ordinary phenomena of diseases, you must note also the diversity of circumstances which, even in the same city, and in the same locality, constantly contribute to vary them in different individuals. To illustrate this by an example: two men, living in the same house, are attacked with acute rheumatism; one of them is a single man, with no cares nor anxieties except on his own account; the other is burdened with a wife and a large family, borne down with the *res augusta domi*, depressed in spirits, and exhausted in frame. Although the symptoms of the disease may closely resemble one another in both cases, yet it would be highly indiscreet to treat them in the same manner. Depletion might be useful in the one, and, although freely employed, yet may be easily borne; in the other it would prove injurious, even in a moderate degree. To cure both of these patients, whilst the general plan must coincide, a different method must be adopted in some particulars. The physician must therefore possess not only a distinct idea of the disease, but he must endeavour to become acquainted with the state of the body in which it found the patient; and with the causes which may have contributed to disturb or injure the ordinary functions, and to predispose it to the attack under which it is labouring; for it must be recollected, that every symptom is not the effect of the immediate exciting cause of the disease, but that some symptoms are the consequences of previous deviations from ordinary health.

I might now, gentlemen, proceed to point out to you the method of investigating diseases; in what manner you are to recognize and to separate symptoms constituting the disease and inseparable from it, from those which are only of occasional occurrence; how you are to be guided in forming your diagnosis, to give the disease a name, and to ar-

range it with its fellows in a nosological sense; how to discriminate the signs which may enable you to predict the event, and acquire that tact which always obtains reputation to the practitioner—skill in prognosis; and, finally, on what grounds you are to found your claims for public confidence, in the performance of the important and responsible duties to which you have dedicated yourselves. But as these are to constitute the business of our frequent meetings in this place, they will, necessarily, form the subject matter of the discourses which I propose to deliver as we proceed in the performance of the task allotted to us, respectively, as teacher and as pupils. In urging you to improve the present opportunity of acquiring the habit of attention and close observation in the examination of diseases, which will make the retrospect of your time spent here an object of satisfaction and pleasure, it shall be my endeavour to make my instructions clear and perspicuous to the least informed amongst you; and whilst I trust you shall be stimulated by my anxiety to set you an example of diligence and attention, you will also be convinced, that the man who undertakes the practice of the profession of medicine, commences a course of study which can only terminate with his life.

REPORTS OF CASES OCCURRING AT PUBLIC INSTITUTIONS.

LONDON HOSPITAL.

*Strangulated Scrotal Hernia, twice operated on.
Death—Post-mortem Examination.*

WILLIAM KING, aged 24, was brought into the hospital July 7th, about one o'clock, with a large strangulated scrotal hernia on the right side. It occurred while lifting a deal plank, about two hours ago, and has since rapidly increased in size. He has never been before subject to hernia. The tumor is very large and tense, and extremely painful; no impulse is communicated to it in coughing. He rejects every thing, his countenance expresses much anxiety, and he complains of pain in the abdomen. His bowels have not been opened since the occurrence of the hernia. The taxis was used without effect.

Ordered warm Bath, 100° Fahr.

While in the bath, further attempts were made to reduce the hernia, but without success. At two o'clock he was carried into the operating theatre. Mr. Luke made an incision, of about four inches, in the direc-

tion of the inguinal canal, and extending to the upper part of the tumor, and then carefully cut down to the neck of the sac, which the tendon of the obliquus externus was distinctly observed tightly girding, so that it was impossible to introduce a director between them; the stricture was therefore divided from without, by means of the point of a scalpel, and then, without opening the sac, the intestines were returned into the abdomen, on which the man immediately expressed himself relieved. The edges of the wound were approximated by two sutures; it was dressed, and a compress applied with a spica bandage.

4 P.M.—Sickness less; slight tenderness of the abdomen. Pulse 84.

V. S. ad $\overline{\text{xxvi}}$:

8 P.M.—Magnes. Sulph. $\overline{\text{3ii}}$.

Aq. Menth. Piper. $\overline{\text{3j}}$.

Syrupi Simp., $\overline{\text{3j}}$.

Cap. 2dis horis donec alvus responderit.

10 P.M.—His bowels have been open twice; the last motion contained a small quantity of blood; skin hot; pulse soft; slight tenderness of abdomen.

Ordered forty leeches to the abdomen.

Cal. gr. i. c. Op. gr. $\frac{1}{2}$ 2dis horis.

8th.—He has slept during the morning. Abdomen slightly tender; pulse 90, and soft.

Rep. Mist. et Pil. tertiis horis.

9th.—He has passed a good night; bowels freely open; wound rather painful.

10th.—He has passed a restless night; much troubled with flatus; bowels not open; abdomen tender; tongue white.

Hirud. xx. abdom. Ol. Ricini, $\overline{\text{3ss}}$.

11th.—No tenderness of the abdomen. The wound was dressed, and looked very well.

Vespere.—He complained of pain and tenderness of the skin on the right side of the abdomen, which was relieved by the application of twenty leeches. The Goulard lotion to be applied to the part.

12th.—Bowels freely open; tongue cleaner; skin less painful.

13th.—Has passed a restless night, and still complains of pain in his side.

Hirud. xx.

14th.—Pain in the side much relieved.

Porter, one pint daily.

The wound continued to heal very slowly, and a large sinus, nearly the length of a probe, was found to communicate with it, from which there was a great discharge of matter.

August 26th.—The sinus and wound nearly healed. About eleven o'clock at night he

complained of being unwell. Four o'clock the next morning he began to vomit; immediately afterwards the hernia descended; his sickness continued; the abdomen and tumor became painful; the pulse small, and quick, and countenance anxious; skin bathed in perspiration. The taxis was used in a warm bath, but failed. About eight o'clock Mr. Luke made some further attempts at reduction, but without success.

Ordered Ol. Ricini, ℥j. and a freezing mixture to be kept applied to the swelling.

On the failure of this, the operation was again proposed and acceded to. An incision was made a little to the inside of the former, down to the neck of the sac, through parts thickened from the inflammation consequent upon the last operation; and attempts were made to reduce its contents without avail. It therefore became necessary to open the sac; on doing which, eight or ten inches of dark-coloured and collapsed intestine, in a state of engorgement, were exposed. The stricture appeared to have been effectually divided, so that a finger could with the greatest ease be introduced into the abdomen. Much difficulty was experienced, however, in returning the intestine, and repeated failures preceded the last and successful effort, from the immense thickness of its coats not admitting of its easy passage through the freely divided stricture. It was at last returned by degrees, and the wound closed with sutures and dressed; pressure being made over the whole with a truss, to prevent reprotrusion.

[He continued to sink gradually, and died on the 7th of September.]

Examination of the Body, 2 P.M.—Upon opening the abdomen, the intestines appeared distended with flatus and were firmly agglutinated by lymph of a yellow colour; their peritoneal surface was very much inflamed; a portion of ileum of a dark colour was adherent to the internal ring; about an inch from the ring a contraction was observed in the ileum, which was thickened; the intestines beyond were not so much distended, or inflamed. The sac in the scrotum was inflamed and thickened, and at the bottom was observed the testicle, so that the opening to the tunica vaginalis had never closed, although no descent of intestine had taken place before the day that he was admitted. There was about a quart of pus in the cavity of the abdomen. The left testicle was situated just outside the external ring, and was small in size.

Fracture of the Skull—Trephined.

—Perry, aged 73, was brought into the London Hospital, August 24th, about two o'clock in the afternoon, having fallen into a ship's hold, the depth of which was

about twenty-five feet. There was a wound through the scalp and temporal muscle two inches in extent, situated above the anterior inferior angle of the parietal bone on the left side; the bone was denuded of its pericranium, and there was a fracture without depression, from the edges of which blood was oozing. There was also a wound through the scalp, in the same situation, on the other side; a slight hæmorrhage had taken place from the left ear. He was sensible; his pupils were rather contracted, and his pulse was quick, small, and irregular. His head was ordered to be shaved, cold lotion to be kept applied to it, and Cal. gr. ii. ter die sumend.

Vespere.—He had gradually become totally insensible, his respiration was laborious, and his pupils were more contracted—the left in a greater degree than the right. Some more bleeding had also taken place from the left ear.

V. S. ad ℥xviii.

25th.—He was completely insensible; pulse irregular and weak; pupils contracted, the left still more so than the right. As, from the situation of the fracture and the symptoms, effusion of blood upon the dura mater, from rupture of the spinous artery or one of its branches, was suspected, after a consultation it was determined to trephine. Mr. Hamilton enlarged the wound, and performed the operation over the seat of the fracture. Upon the removal of a circular piece of bone, the pulsation of the brain was observed, and a considerable quantity of coagulated blood, some of which was with difficulty detached from the dura mater with the handle of a scalpel. A large groove for the lodgment of a vessel was observed in the portion of bone which had been removed. Another piece of bone contiguous to, but above and rather behind the last, was then taken away, which was followed for a short time by some arterial bleeding. After the operation the man's pulse was fuller.

Ordered Cal. gr. v. quartis horis.

26th.—His mouth was slightly affected; he appeared more sensible, but was unable to speak: pulse regular, and soft.

Cal. gr. iii. octavis horis.

27th.—He appeared partly sensible, and could mutter a few words; he had passed a restless night.

28th.—His mouth was very sore; he understood a little when spoken to, and had a calm pulse.

Hirud. xii. capiti.

29th.—Slightly sensible; pulse 85, and soft; mouth very sore.

Rep. Hirud. nocte manequæ. Poullice to the wound, which had an unhealthy aspect. Omit Cal.

30th.—Much the same as yesterday.

31st.—He became quite insensible last night, but was a little improved this morning; pulse irregular and weak.

September 1st.—Quite insensible; takes no nourishment; pulse weaker.

2d.—Died at eight o'clock this morning.

3 P.M. *Examination of the Body.*—The wound in the scalp was in an unhealthy state. Upon removing the calvarium, some dark-coloured blood was observed upon the dura mater on the right side, and a small quantity on the left. The dura mater did not appear inflamed; when removed, the surface of the brain underneath that part of the skull which had been trephined, was, to a considerable extent, in a sloughy state; the substance of the brain was rather more vascular than natural. The fracture extended, on the right side, from the anterior inferior angle of the parietal bone, in two directions; one through the squamous and petrous portions of the temporal bone, the other through the temporal portion of the sphenoid; then uniting and passing through the sella turcica to the anterior inferior angle of the left parietal bone.

WESTERN DISPENSARY,

23, CHARLES-STREET, PARLIAMENT-STREET, WESTMINSTER.

Typhus Fever successfully treated with Tartar Emetic in large doses.

ANN EDWARDS, æt. 30, was admitted under the care of Dr. Lilburn, on the 3d September, 1831, while labouring under typhus fever in a very severe form. The patient had been confined four months since, of her second child, who is still living. She complains of great pain in the head, with occasional delirium; the countenance is pale and collapsed; tongue black, and dry; the teeth covered with sordes; pulse at the wrist small, irregular, beating 136 times in a minute; respiration hurried; secretion of milk suppressed. About ten days since, she was labouring under diarrhoea, which ceased spontaneously. The bowels are at present irregular; urine scanty. Petechiæ have appeared on the neck, arms, and body. The patient lies supine, and appears perfectly insensible to every thing around her, unless powerfully excited. The head to be shaved, and kept constantly cool with cold water.

Applic. Hirudines, vi. temporibus.

R Sulph. Magnesicæ, ʒij. Aquæ ʒj. M. bis indies sumend.

September 4th.—Continues much the same. The bowels have been opened twice.

Cont. remedia.

5th.—Much the same. The cold water to the head to be continued, and the follow-

ing medicine to be given, unless vomiting be produced.

R Antimonii Tartarizati, gr. j.

Syrupi Scillæ, ʒj. M. 4ta quaque horâ s.

6th.—The first dose of the medicine occasioned nausea, but it has been continued regularly, as directed. The tongue is less hard, but continues black; has had no alvine evacuation; urine still very scanty, and high-coloured; pulse 122; the skin is not quite so dry, but no sensible perspiration.

Cont. remedia.

7th.—Appears a little better; has less delirium, and the thirst is not quite so urgent; tongue beginning to get cleaner.

Pergat.

R Antimonii Tart. gr. j.

Syrupi Scillæ, ʒj. M. 2da quaque horâ s.

8th.—The bowels have acted twice; delirium and thirst abated; tongue moister; pulse 110.

Cont. aqua font. Capiti.

Cont. Mist. Ant. Tart. 2da quaque horâ.

9th.—The petechiæ are less livid; pulse soft and regular, 110; thirst lessened; has no vomiting; no alvine evacuation.

R Antim. Tart. gr. ʒss.

Syr. Scillæ, ʒj. M. 2dis horis s.

10th.—Slept well during the night, and is in every respect better this day; has had no return of delirium the last twenty-four hours. Pulse 100; the medicine produces nausea; she is able to sit up in bed.

Cont. Mist. Ant. Tart. co. 2dis horis. s.

12th.—The medicine occasioned vomiting last night, and was in consequence discontinued; she is better, and able to sit up in bed; one alvine discharge; pulse 100.

Cont. Aquâ capit. applicanda.

13th.—Continues improving.

Capt. Magnesicæ, gr. iij. ex aquâ bis indies.

23d.—Has continued to improve daily since the last report, and is now able to walk to the Dispensary with ease; appetite improving; tongue clean; pulse 76; bowels opened once or twice daily; urine natural in colour and quantity.

30th Sept. 1831.—Discharged cured.

NOTICE.

The name of the patient in the case of Aneurism inserted in our last, was different from that in the Clinical Observations upon it. This was a mistake on the part of the journal from which they were taken.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES
ON
THE THEORY AND PRACTICE OF
MEDICINE ;

Delivered at the London University,

BY DR. ELLIOTSON.

LECTURE IV.

Recapitulation — Predisposing and Exciting Causes of Disease—Temperaments—Idiosyncrasy—Semeiology or Symptomatology—Diagnosis—Prognosis.

I FEAR, gentlemen, that the first three or four lectures will be considered by you exceedingly dry ; but before entering upon the subject of any particular disease, it is quite necessary that you should understand the various terms which will be employed, and I therefore trust that you will not be tired of hearing the definitions which I feel myself under the necessity of giving.

I stated that pathology, or the doctrine of disease, was divided into two branches, general and special ; the latter relating to any particular disease, and the former to diseases in general. The observations I am now making are preparatory to entering upon special pathology—the nature, history, causes, and treatment of any particular diseases. I stated that general pathology was usually said to consist of four parts ;—one treating of diseases in general, their resemblances, and their differences ; another of their symptoms ; another of their causes ; and a fourth of their treatment. I have made all the general observations which I think necessary respecting the first division of general pathology—the differences and similarities between various diseases.

I proceeded to consider in the last lecture the various causes of disease in general. I

spoke both of those which predispose to disease, *causæ predisponentes*, or *proeugmentæ*, and those which are called occasional, exciting, or *causæ proeatacticæ*. The exciting causes of disease have been arranged by many in three classes ;—those which stimulate, those which depress, and those which act only physically or physico-chemically, independently of stimulating or depressing. I mentioned that the chief sources of the exciting causes of disease were derived, in the first place, from what appear to have been absurdly enough called “ the non-naturals ;” namely, the air we breathe, food and drink, the fluids proper to be retained in the body and those which are proper to be discharged, motion and rest, sleep and watching, and the passions of the mind.

With respect to the first of these non-naturals, the *air*, it may injure the body by its weight or levity, by the various electrical qualities which it may possess, by its temperature, by its dryness, and by its moisture. Various winds have various effects upon the human body of the most curious kind, according to the countries, or districts, or parts, over which they pass. With respect to temperature, it injures the body not only by its height or lowness, but also by its vicissitudes, and not only so, but accordingly as it is applied partially or generally to the body. A temperature that would do no harm if it were continued, would be productive of serious mischief if it suddenly succeeded an opposite temperature. A temperature which would do no harm if applied throughout the body, frequently does great harm if applied partially. Every body knows the danger of suddenly cooling, if the body be over heated and fatigued ; and of a draught applied to any one part of the body. Included, perhaps, under the head of air, may be mentioned various effluvia and various odours, as they are transmitted through the air.

Upon *food and drink*, another source of disease, I need say but very little ; they may

be injurious either by their quantity or quality.

As to what are called *excreta* and *retenta*—to speak first of *retenta*: the great thing here alluded to by old authors is the blood, and it was supposed formerly that it might greatly injure the body mechanically by its excess, either absolute or relative, so that *plethora* formerly occupied a very prominent part among the causes of disease. You will find some curious distinctions made by old authors on the subject of *plethora*. They called it absolute or true, or *ad vires*, or *ad vasa*, when the quantity of blood was absolutely in excess; they called it *apparens* when the blood was in its natural quantity, but expanded. They fancied it might be expanded by heat, and in that way a temporary *plethora* be induced. *Plethora*, too, was divided again into a third variety—*relative*. When there was no actual increase of blood, when the blood was not expanded improperly by heat, but when the space in which it moved had become too small, this was called relative *plethora*, or *plethora ad spatium*; where the vessels, it was supposed, became contracted, and the blood was in excess to merely the contracted space. *Plethora*, however, certainly may be either *general* or *local*. A local *plethora* is what in modern language is called an inflammation or congestion, just as the case may be. When the blood is really in excess, I believe that it is generally of too rich a quality; that there is too little of its watery portion, and too much of the crassamentum. I need not say that the opposite of *plethora* is *inani-tion*. This is a state which is induced by excessive discharges, or from the want of food; so that the blood which was in the body is let out, or the blood which naturally escapes in the various excretions is not replaced. Anæmia, or bloodlessness, but more properly a watery state of the blood, will arise from an ill understood, I may say, not at all understood, state of the system, in which, although food is taken, nourishment is but very sparingly extracted from it. Cases of this description are seen continually: chlorosis is one of this kind. But the blood sometimes certainly is in fault with regard to its constituents, not merely as to whether it is too rich or too poor, but, as it would appear by some recent experiments of a friend of mine, Dr. Stevens, who is about to publish a work on Fever, and Dr. Clanny, by the saline ingredients erring in their quantity; so that the blood, in many cases of disease, is absolutely deficient in its saline particles. It is evident, however, that diseases of the solids themselves will sometimes cause these aberrations of the blood; so that the blood itself is not the cause of the disease. It may become an instrument of farther disease, though disease of the solids originally may

have given rise to the aberration of the vital fluid.

With respect, however, to the excreta, you may easily conceive how excessive discharges will occasion various diseases. The excessive discharge may consist of blood, of bile, of secretion from the alimentary canal, fæces, of urine, of perspiration, of saliva—that, however, seldom does much harm—and of semen. These are the fluids which particularly escape from the body, and the escape of which may do harm. But with regard to the latter, the discharge of semen, although one must suppose that the simple excessive loss of the fluid must be injurious, yet it is very certain that the mode in which that fluid is lost exerts a very great influence upon the constitution.

In regard to *motion* and *rest*, I need not point out the ill effects of sluggishness on the one hand, nor of fatigue on the other. Nor with respect to *sleep* and *watching* need I make any remarks, for they come under the same head as *motion* and *rest*; *sleep* and *watching* being to the brain, what *repose* and *motion* are to the body.

With respect to the *passions of the mind*, I mentioned in the last lecture that they are a frightful source of disease; much more so than is commonly imagined. An immense number of cases of disease of the heart and disease within the abdomen, as well as of the brain itself, arise, I am certain, from unpleasant passions of the mind. However, it is not merely unpleasant passions that affect the body injuriously—*violent* emotions of the most pleasurable kind will sometimes operate in the same way. History relates many accounts of persons who have died from excessive joy.

Besides those circumstances, however, which I have just mentioned, the body is liable to injury from two very common sources, one of which is *poison* of various sorts, which poison may enter the system by the surface, may enter it by the breath through the medium of the lungs, or may enter it by being swallowed; and it is a very curious fact, that many which act offensively when admitted into the body one way, have no effect when admitted in another. I believe it is a fact, that the poison of hydrophobia, or the poison of a serpent, may be swallowed with the most perfect impunity.

In addition to poison, the body suffers much from *mechanical injuries*—mechanical injury, of course, is a cause that may affect almost any part of the body.

Among the *causes* of disease which chiefly act by giving a predisposition, we may mention that of age. All periods of life are subject to their own diseases, whether we divide them with Shakspeare into seven, or with those authors who mention five, or those who mention more. Every

age is particularly liable to certain diseases: for example, you rarely see gout in an infant, nor is it common for old persons to have the symptoms of acute hydrocephalus. In short, every age seems marked out as particularly liable to be, if not destroyed, at least impaired, by particular diseases. The same is the case with respect to sex: each sex is particularly liable to its own affections. Hysteria, which occurs only now and then in the male, occurs far more frequently in the female, and even when there is reason to suppose an affection of the uterus. Of course there are certain diseases which can affect but one sex.

As to temperament, disease depends much upon it. We are all of some temperament, or some combination of temperaments, but excess of one temperament gives a great liability to disease. You know that the usual divisions of temperaments are four—the sanguineous, the melancholic, the phlegmatic, and the choleric. The sanguineous is marked by smoothness of skin, softness of hair, a quick pulse, a warm surface, great excitability of the whole frame, and generally a fair skin with florid complexion. The melancholic, on the other hand, is marked by a slow pulse, by a dark swarthy complexion, dark and strong hair, and less susceptibility of emotion—that is to say, of sudden violent emotion, although when certain emotions take place they are said to be more continued. The phlegmatic is marked by torpidity, paleness, and flabbiness. The choleric is characterized by reddish hair and great excitability. However, these divisions, although they were made by the ancients, are not so much attended to now. We certainly often see these temperaments strongly marked, but they are all infinitely combined.

An attempt has been made within these few years to divide temperaments differently, according to the activity of particular parts. For instance, some persons have the chief activity in the head; they have a large intellectual development of the head, as some people say, and that would be called perhaps the *cerebral* temperament. Others, again, have a large broad chest, with a considerable development of all the muscles, and this is called the *thoracic* or *muscular* temperament. And again, others are sluggish, prone to eating and drinking, with large bellies, and are said to have the *abdominal* temperament. Now it is rather an abuse of terms to call these temperaments, for I think the word *temperament* rather refers to the constitution and character of the whole frame together; yet there is no doubt that these divisions occur, for you see some persons all intellect, others all muscle and chest, and you see some portly, with their big bellies and lean pates, their heads suffering in proportion. In truth, Dr. Tho-

mas entitles his work, *Physiologie des Temperaments ou Constitutions*.

However, whether you choose to call these temperaments or not, it is well to know that these persons will suffer various diseases, according to the division under which they come, just as is the case with regard to those who are of a sanguineous, phlegmatic, choleric, or melancholic temperament. They will be particularly liable to diseases of the head if they be of the cerebral conformation; they will be subject to affections of the chest, not of a phthisical, but of an inflammatory kind, if they have a full thorax; and of course they will be subject to various hepatic, and other abdominal diseases, if the abdomen gain the sway. It is worth while to attend to this other division of temperament, although, perhaps, the term itself may be objectionable.

Besides original temperament, acquired peculiarities take place by a long residence in a particular climate: by long residence in a particular spot certain dispositions of the body are engendered, and a second nature, if I may so say, is produced. The various occupations of life have the same effect; the various trades have their various diseases. On this subject you cannot, I believe, read better works than Rammazini's and Thackrah's. Custom and habit, whether referable to trade or situation, or action, or any other circumstance, have also very great effect in producing or in preventing the cure of disease. For example, if a person be in the habit of dram-drinking, and has a sore, nothing is more common than to see that sore not heal, in spite of the best surgical treatment, till the person is allowed his dram. After a surgical operation a person has been known to sink through the surgeon not having been aware that the individual had indulged in some bad custom until it had become a bad habit. From the want of a patient being allowed a quantity of gin in the course of a day, he has died after an operation, whereas he otherwise might have done well. This has been strikingly shewn in other cases where the knowledge was happily attained; and a good allowance of gin after some severe accident has caused every thing to go on well, though the patient at first appeared sinking. Bad habits are, therefore, sometimes to be indulged, although they should certainly never be acquired.

Independently of what is called temperament, an individual may have a particular disposition not acquired; it may be born with him, and be hereditary. A peculiarity is sometimes so exceedingly singular, so totally different from what we observe in other people, that it is called *idiosyncrasy*. It is nothing more than a peculiarity either original or acquired by habit, and sometimes it is only connate, and sometimes hereditary. As an instance of this, you will some-

times find a person who cannot eat a certain article of food. I recollect seeing a young woman who could eat the hardest salt beef, and digest it well; but if she took a raspberry, or currant, or any fruit, she was instantly thrown into the most violent spasms of the stomach, so that a stranger would have fancied her life in danger. These are called idiosyncracies, and it is of great use to know them, because some persons are peculiarly affected by certain remedies; and that which is a proper remedy for the disease may be improper for a particular patient.

So much, therefore, gentlemen, with respect to the causes of disease in general—to general *ætiology*; and I will now proceed to consider the third branch of general pathology—the symptoms of disease in general—which is called *semeiology* or *symptomatology*.

I believe I mentioned that *symptoms* are every thing which are observed in a patient out of the course of health; *singulæ quæ in agro præter naturam observantur res*. The most evident, the most constant of these, are put together, and said to constitute the disease. You will recollect that the disease is not the cause of the symptoms, but that the disease is the collection of symptoms. I mentioned this, and illustrated it with respect to jaundice and to epilepsy, the outward signs of which are jaundice and dropsy, while the inward state is the proximate cause.

Now these symptoms may be *essential*, they may be what is called *pathognomonic*, and they may be *accidental*. The *essential* symptoms of disease are those which are necessary to make the disease—to constitute the idea of the disease. You cannot, for instance, suppose a patient to have pleurisy unless there be a degree of feverishness, with sharp pain of the side, increased upon respiration, together with a cough. These symptoms would be called the *essential* symptoms of the disease, yet no one of them would make the disease. A patient may have feverishness without pleurisy; or a sharp pain in his side without pleurisy, because it may be muscular or it may be neuralgic; or again, he may have cough without any pleurisy. These are then, you perceive, *essential* to the disease altogether, but no one of them constitutes it. If, however, a symptom be so important to the disease that this cannot be present without it, then it is called *pathognomonic*—a symptom without which you could have no conception of the existence of the disease. There are, however, but very few of these symptoms. In jaundice, the yellowness of the skin, of the *sclerótica*, and of the nails, is *pathognomonic*. Without making any farther inquiry, you may be sure that the patient labours under jaundice; but in general we make out the

disease from the groups of *essential* symptoms, and from taking into consideration every circumstance of the case. Besides these symptoms, others are *accidental*. Many cases have symptoms which are merely *accidental*, and are not necessary at all to the disease: the disease has frequently existed without them.

You will find symptoms also spoken of as *positive* and *negative*; and it is of great use to attend to the latter. A *negative* symptom is perhaps, an improper expression: a symptom must, properly speaking, be *positive*, but, from the absence of certain circumstances, of certain symptoms, you make out frequently the nature of a disease. If there be two diseases with certain symptoms common to both, but one of them has a symptom which the other never has, then, if that symptom be absent, it enables you to make out the true nature of the case. Hence the absence of certain symptoms is frequently of as great importance to be attended to as the presence of others.

Now, from the presence of the symptoms chiefly, but not entirely, we make out the character of the disease; and the determination of the character, the name and nature of the disease, is called the *diagnosis*. To speak again of jaundice, from the yellowness of the skin, the whiteness of the *fæces*, and the dark colour of the urine, you make your diagnosis, and say the disease is jaundice, although, indeed, you may do so merely from the yellowness of the skin and the *sclerótica*. But you will frequently find your diagnosis is not easily made from the symptoms alone—you must look into the exciting and predisposing causes of the disease: you must ascertain what the patient is likely to have—what predisposition he has; you must also ascertain to what exciting cause he has been exposed; and then conceiving what it is likely would ensue, and observing what actually has ensued, as far as you can judge, you are enabled much better to form a conclusion as to the real character of the affection. You will find your diagnosis also materially assisted by attending to the history of the case; not merely observing the symptoms that present themselves to you, but inquiring carefully of the patient the whole story from the beginning. You will thus ascertain whether these circumstances confirm what you suppose to be the nature of the case. You will also find it of great importance, in making out the character of the disease, to learn the effects of any previous treatment that may have been adopted. If you learn that vigorous treatment has been properly employed, and has had no effect whatever, you would doubt very much as to the propriety of the view which had been taken with respect to the nature of the affection. In making a diagnosis all these points are to be scrupulously attended to.

It is in making an accurate, careful diagnosis, that the medical practitioner chiefly shines. When the nature of a disease is once ascertained, it is no difficult matter to treat it; other qualities of mind are then required—frequently only courage, or mere perseverance—but it is in making a diagnosis, in ascertaining the character of a disease, that the scientific practitioner outshines the inferior. Unfortunately this is a point not attended to as it ought to be. Many persons pride themselves in being good practitioners, because, without knowing what is the matter, they can say what will do good. It is an unscientific way of proceeding, and, if I could not practise better for making a good diagnosis, still I would be as particular on that point as possible, for the sake of observing a good general rule—for the sake of endeavouring to treat the patient better than I otherwise could, notwithstanding all my conceit—and for the purpose of being ready to meet any unexpected emergency that might arise. A medical man who will not take the trouble to establish a diagnosis, is just like a surgeon who will not condescend to learn the anatomy of hernia, but who says that he knows if he cuts this way and cuts that way, he shall liberate the entangled parts, and do the operation as well as the best. I have witnessed this; but, then, what are such men when a difficulty arises? They are lost in perplexity, and glad to apply to those who know better. It is impossible to be too minute in making a diagnosis.

You have not only to make a diagnosis as to the general character of the disease, but you have to ascertain what variety of the affection it is—whether it is one with strength or weakness—and to weigh the minutest circumstances respecting the case. This is, perhaps, an exercise of patience, but it is an exercise highly gratifying; especially when you find you have made a correct diagnosis.

The judgment you form as to what will happen in a case, is called *prognosis*. In order to make a very correct prognosis, it is best to make an accurate diagnosis; for if you do not know what the affection is, you will often be unable to tell how it is likely to terminate. For the sake of making a prognosis you must observe all the symptoms, and learn the history of the case, exactly as in making a diagnosis; but there is something more to be done than that—you must know the direct tendency of the disease, the course which the disease is always inclined to run, the course which it is likely to run in the particular individual, according to his age, according to the sex, according to his previous habits, according to all those circumstances which I have previously mentioned as to his individual peculiarities, and accordingly as you have it in your power to

put into practice requisite curative means. In some cases, if we were allowed to practise our art freely, we should make a favourable prognosis; but our hands being tied, as they sometimes are, when others ill informed or inactive are called in over us, we must give an unfavourable prognosis, simply because the patient must be allowed to die. In making a prognosis there is frequently less skill required than in establishing a diagnosis; for some persons, with a sort of tact, will tell whether an individual is in danger or not without knowing what is the matter with him. Many persons who have no knowledge of medicine, or at least very little, have such strong perceptions, that, from the aspect of an individual, and from general observations of their own, they are enabled to give a very correct prognosis, either favourable or unfavourable. This I know to be the case. There are a great many intelligent officers who, from seeing their men fall around them in battle, sick in hospitals, have become, in one sense of the term, good doctors; and though they are not able to cure the disease, or tell what is the matter, they will be able to give a shrewd and correct guess as to how matters will turn out. But although some people, by nature, are well qualified for this, while others are not, yet the medical man must be taken as he is; and whether he does or does not possess natural sagacity to make a prognosis, it is his duty to make as careful a diagnosis as he can, in order that he may make as good a prognosis as possible. If his intellect be not of an acute description, yet, by knowing the case, and by the aid of science and minute observation, he will be able to form as good an opinion as the man who by nature is qualified for these things; and if with science and observation is combined native sagacity, then I need not say that his prognosis will be much superior to that of the individual who only trusts to his natural powers.

You therefore see what is meant by diagnosis and what by prognosis; and I cannot urge upon you too strongly the most careful attention in establishing the former. Whether you can cure the patient or not, you should make it a solemn rule to investigate the case to the utmost. It is only by this that we can profit ourselves, or that those who come after us can profit. If we be not careful we cannot advance science, and the next generation will be none the better for us.

With respect now to the symptoms of disease on which diagnosis and prognosis are in a great measure to be founded. The symptoms of disease may be divided, perhaps, in one point of view, into two kinds—those which are discoverable by the patient only, and those which are discoverable by by-standers also, or only.

Now there are some symptoms which a patient alone can ascertain—for example, his feelings. He it is that feels the pain, and it is a lucky circumstance that it is so; for if the doctor felt the pain as well as the patient, there are but few who could stand practising the profession. We know little about pain but from the patient's account; and in many cases in public practice we are deceived. We have, however, only done our duty in listening to the patient's account.

With respect to *pain*, it is of various kinds; it may be sharp, stabbing, darting, shooting, lancing. These are all words used by patients. At other times the pain is not of this character, but dull, and then we call it an *ache*; and sometimes patients add the word *pain*, making it *aching-pain*. Sometimes you will have pain described as throbbing and pulsating; and you will hear patients also complain of pricking pain, as though a number of needles were being pressed against them. Now these things are all of great importance to be attended to, because they shew frequently the seat of the affection; and accordingly as a patient describes his pain, as sharp, or dull, or throbbing, or pricking, so you ascertain frequently whether he is telling the truth or not, because you see for other reasons a probability that, if he have pain at all, it is of a particular character, and you ascertain whether his account agrees with what you would, *a priori*, expect him to describe. You will sometimes hear pain spoken of as smarting, and a very high degree of this is broiling. In some affections of the abdomen you hear a patient complain of broiling pain; it appears to be a high degree of smarting, with a sense of burning.

Now if pain be increased by pressure, or by the application of any stimulants, then we say there is *tenderness*; but perhaps the word *tenderness* is more properly restricted to pain increased upon mechanical pressure. There are other feelings continually described by patients, as, for instance, a feeling of dead weight. This is particularly the case with respect to the head. You will sometimes hear persons complain of fullness, as if a part were excessively full; and now and then this sensation arises to such a pitch, that the part feels as if it would burst; and then we call it a feeling of tension. A feeling of tension appears to be a high degree of a feeling of fullness. You will now and then have patients complain of a sensation of pins and needles. It is very different from the sensation of pricking pain, as if needles were being run in; it is as if the pins and needles were rather blunt; it merely gives the lowest sensation of this kind, not amounting to pain. Pricking pain is of a very different character—for instance, that which people frequently complain of from inflam-

mation of the urethra in gonorrhœa; they experience a pricking pain along the urethra; but the sensation experienced when the hands and feet are asleep is not called pain; patients say they feel as if pins and needles were there. You will frequently hear persons declare, that they have an indescribable uneasiness in a part, a sensation which nearly drives them mad; but they will not allow it to be pain. I have known this sensation occur in different parts of the body. I recollect one lady who had it in the neck, so that she was obliged to walk about the room followed by a servant rubbing her neck night and day. Unless this was done the sensation nearly deprived her of her senses, and her countenance betrayed the greatest distress. You will find other sensations spoken of by patients—a creeping, a crawling, or a feeling as if water were trickling down them. There is also a symptom which approaches nearly to pain, itching and tingling, which may be almost insupportable. Tingling is a high degree, I imagine, of what is called itching, united with a sense of pricking. In regard to other sensations, there is nausea felt in one part—the stomach; and now and then persons have an excessive sensibility of one particular sense—of the eye or the ear.

Now all these are symptoms which the patient alone can know any thing about. We all know something about them, because we are more or less ill at some part of our lives; but the medical attendant must take the patient's word for these sensations, at least he cannot ascertain the existence of them directly—he can only ascertain by other symptoms whether the patient is probably telling the truth.

Besides these, people have a feeling of great exhaustion, of great debility, and this is a point strictly to be attended to in forming the prognosis in an acute disease, for sometimes it is a fatal symptom. When a patient, for example, after inflammation of the bowels has no pain, but a feeble pulse, and complains that he is so weak that he feels as if he should die—that he never felt such weakness in his life—you may be almost sure that he will be dead before the next day. On the other hand, this feeling is very deceptive. Women are subject to a sinking sensation at the epigastrium; they tell you they feel as if they had no inside, and they are sure they are about to die, but the feeling is quite delusive. You might in the former case, after an acute disease, judge from seeing all, or the greater part of the symptoms decline, that the patient would soon get well, and that this feeling of weakness was nothing more than might be expected after severe indisposition; but you must take into account other symptoms, particularly the weakness of the pulse. But with respect to these women you find

the pulse good, and they are able to walk about notwithstanding all the depressive feelings of which they complain. It is a very remarkable circumstance, and I shall find it necessary to draw your attention to it when speaking of diseases of the stomach, and of hysterical affections. Patients also alone can be conscious of drowsiness, want of appetite, inordinate appetite, and depraved appetite, although with respect to many of these things you can often by other circumstances ascertain whether they are telling the truth or not. It is to the patient, likewise, that you must trust for an account of the existence of tenesmus and of strangury—a frequent desire to go to stool, and a painful and frequent desire to make water. All these are instances of symptoms, of which you must receive an account from the patient himself.

There are some such symptoms, too, which are derived from other senses than those of general feelings, and these are referable to the ear. Patients will continually complain of the most violent beating pulsation in their head, and frequently, too, of a snapping and cracking there. Such symptoms undoubtedly do exist, but we can take no cognizance of them. With respect to sight, you must depend on the patient's account for the occurrence of flashes of light before the eyes; and for the symptom so common in many diseases—moats floating before the eyes, and for double vision or diplopia; and likewise for the symptoms of giddiness or vertigo. On the patient also you must depend for symptoms with regard to taste; some have a bitter nauseous taste in their mouth, of which you cannot judge. So with respect to smell; now and then persons have a most disgusting disagreeable smell, which no other person can notice. There was a case of hydrophobia at Guy's hospital, in which there was an instance of an accidental symptom, and that a symptom to be ascertained only by the patient—the patient experienced the most disgusting smell. You will find in cases of insanity that this occasionally happens. Now and then the smell which the patient perceives may be noticed by other persons, because it arises from some disease within the nose.

There are still other symptoms of which the patient alone can give an account—a defect in the senses, a loss of sight, a loss of taste, a loss of hearing; for all this you must depend much on his account. So with respect to many mental circumstances—the loss of many desires, and a feeling of strong desires; for all this you must rely upon the patient. You see, therefore, that in regard to symptoms, they may be divided into two classes, the first of which are evident to the patient alone, and the second those which are perceptible to the practitioner also or only.

At the next lecture I shall proceed to consider those which are of the latter description.

ON THE MEDICAL TREATMENT OF INSANITY.

Being one of the Croonian Lectures delivered before the College of Physicians, in May, 1831,

By EDWARD J. SEYMOUR, M.D.
Physician to St. George's Hospital.

— — —
Blood-letting—Mercury—Cold applications to the Head—Counter-irritation—Sedatives—(Acetate of Morphia—Belladonna, &c.)—Arsenic—Camphor—Purgatives—Diet.

THE application of medicine to mental disease must, of course, be directed, in the first instance, to the nature of the attack. It will become necessary carefully to inquire whether the brain is primarily or secondarily affected, and whether such affection is or is not connected with organic lesion. The physical causes must be carefully separated from the moral, and due weight assigned to each. If, on accurate inquiry, the patient has been exposed to causes sufficient to produce inflammation of the brain and redness of the countenance, injection of the conjunctiva and heat of skin very early in the disease point out increased vascular action, with increased power; antiphlogistic remedies, with blood-letting, principally from the jugular vein, are to be employed; and in such cases, and probably only in such cases, mercury may be employed, to affect the system; such cases will often recover. In the summer of 1827, I had occasion to visit a gentleman, æt. 30, whom I found in the following condition. He was lying on a sofa, in a state of great agitation, and complaining that he had committed some great crime, and was the object of a conspiracy. He complained of pain in the head, and would not permit me to feel the temperature of it. The pulse was quick and oppressed, and I recommended that he should lose blood. The first bleeding was borne very ill, but the second, to the amount of sixteen ounces, was attended with some relief, Cold was applied frequently to the head, and blood abstracted by cupping every day for several days, during which time he took calomel every four hours. As the mercury began to affect the mouth, a visible change in the mental malady came on; this gradually increased in the most favourable manner, and the patient entirely recovered, nor has he suffered the smallest relapse since that time. I had the advantage of the assistance of Mr. Tupper in this case. This case is only, however, an example of a few where the mental disease is going on in consequence of increased vascular action; in the great majority of cases the functions of the brain, in mental derangement, are increased in force, while the circulation is depressed, extremely quick and feeble, and the action

of the heart giving way at the smallest abstraction of blood; and yet these are often attended with raving delirium, great increase of muscular force, and are, in fact, what are termed high cases. The consequence, I am informed, of such practice, is either the more frequent returns of the high stage, or the patient sinks into one approaching idiocy.

"At the admission," says Pinel, "of any lunatic into the hospital, great care is taken to interrogate the relations on the subject of blood-letting; and the question is asked, whether it has been employed, and what was the result? The replies the most constantly made attest that the condition of the lunatic has constantly become worse immediately after bleeding." I think I ought not to omit a curious fact which occurred in the year 1813. Two young persons, of a similar age and temperament, arrived the same day; one of them had not been bled, and her cure was effected in two months; a copious bleeding having been exhibited to the other, she was reduced to a kind of idiocy, and did not recover the use of speech until near the fifth month; her complete re-establishment was not effected until nine months. We saw afterwards a singular example of a melancholic patient, who had been bled five times from the foot and three times from the jugular vein, and had fallen afterwards into such a state of stupor and debility that she passed several days without taking any nourishment." Dr. Haslam informs us, that it is only in the very early stages of the disease that blood-letting is useful, and then he prefers cupping. It is also very remarkable that, according to his testimony, the appearance of the buffy coat on the blood, generally considered to justify such practice, has been found generally absent in cases of lunacy where venesection has been used. In more than two hundred patients, male and female, who were let blood by venesection, there were only six whose blood could be termed *sizy*. The experience of Pinel is very decided against this practice.

The experience of any individual, however zealous, must be extremely limited; and I do not venture, therefore, to detain the College with the result of my personal inquiries. I have endeavoured to obtain the result of medical practice on a large scale, and for this purpose selected Mr. Warburton's house, the White House on Bethnal Green, containing 400 patients, and where the skill of Mr. Beverley, the superintendent, and Mr. Phillips, the resident surgeon, emboldened me to offer to the consideration of the College facts which have resulted from their extensive and assiduous observation, which I could never hope to have obtained from any private source. It is to these gentlemen I am indebted for the principal observations I am enabled to relate.

Messrs. Beverley and Philips state the following as the result of their observations on this subject:—

"The number of patients admitted with vascular excitement, requiring blood-letting, are very few indeed; we seldom or ever use the lancet in cases of excitement, if there is no evident effect upon the brain from increased arterial action, so as to lead us to fear an approaching attack of apoplexy or paralysis. The reason we do not use the lancet in cases without any such symptoms existing of disease going on in the brain, is that we have done so in several instances, and the result was not favourable; the patient became reduced from the loss of blood, and the excitement not abated, the powers of the constitution gave way, the tongue became typhoid, and the patient sank into a state of collapse and died."

As the result, then, of experience in cases of excitement, I presume that these arise from increased nervous energy, not depending on increased action of the heart and arteries, but on increased sensibility of the brain itself, and that blood-letting is not found useful.

Hence physicians have been under the necessity of seeking for means to allay the inordinately increased sensibility principally of course occurring in that division of insanity termed dementia. These remedies are various. I shall commence with cold, which may be administered in three ways—in the form of ice, in the shower-bath, and in a column of water, graduated according to the strength of the patient, and termed the "*douche*," a French word, for which I know of no corresponding one in our language. Of ice to the head, not only in order to diminish vascular excitement, but also to produce a really sedative effect, a diminution of intensity of sensibility of the brain itself, I can speak with some confidence. In the epidemic typhus fever which has recently raged among the lower classes in this town, and which has been of a marked and peculiar character, with scarcely any, if any, stage of excitement, the application of ice in the low maniacal delirium which accompanied it was attended with the happiest effects, and in more than one case appeared to be the principal means of cure; the patient sleeping quietly for hours under an ice cap, who, previously to the use of the remedy, had passed the night in low muttering delirium, or in the constant endeavour to leave his bed. This remedy appeared to me to be useful exactly in proportion as the delirium assumed the maniacal character. The torpor produced by extreme cold may convey a tolerably accurate idea of the modification which the extreme sensibility of the brain may receive from this remedy. The effect which pouring cold water on the head, in cases of affection of the brain with in-

creased vascular action, produces, may be illustrated by the following very remarkable case, which I attended with my friend, Dr. Roupell, physician to the Seaman's Hospital. A young medical man was attacked with symptoms of inflammation of the brain, while pursuing with great ardour his professional studies; and being a medical man he was, of all other persons, the most difficult to treat. Notwithstanding the intense pain in his head, his quick and frequent pulse, he resisted remedies. Venesection he would not submit to, leeches he had an objection to, calomel he thought produced inflammation and ulceration of the mucous membrane of the intestinal canal;—it was proposed to pour cold water from a pitcher over his head; the consequence was diminution of pain, quiet sleep, and, in fact, so beneficial an effect that the patient himself frequently called for a repetition of the remedy. I saw this patient several times, and the impression on my mind was, that to this remedy, and to this alone, he owed his life in that attack.

The shower-bath appears to have a very similar effect, and I am enabled to quote a case of its benefit in mania, from the testimony of the gentlemen to whom I have alluded.

"We have found, in some cases, the shower-bath of great service; but it appears to us, from the experience we have had of it, that it is more beneficial in cases of a very violent nature, with increased vascular excitement, as we have given it a trial in cases of various descriptions, and in some without the slightest benefit.

"There was a case admitted into this establishment, evidently a case that was completely cured by the use of it. A gentleman, aged 30, small, and light complexion, had been studying hard, and constantly confined to one room, was attacked with furious mania; thought he had found out perpetual motion, and that he could make the sun stand still. Pulse very quick, 120, and small; pupils contracted; imagined he could reach any thing he saw, and grasped at them; incessantly talking; tongue furred and dry. We ordered him to go into the shower-bath. His extreme violence put us on our guard, that we got six keepers to take him there. We persuaded him, with much difficulty, to go in, by saying it was only a sentry-box. On hearing that, he immediately went; the door was closed and secured; the shock was so unexpected that he screamed and held his breath for a short time after the shock was over; then gasped, and knocked the sides and the door into pieces, and stepped out; but was immediately secured, rubbed dry, and put to bed. He had a little refreshing sleep during the night. In the morning he vowed vengeance against the doctors for murdering him. We could not prevail upon

him this day to go into the bath, which obliged us to confine and carry him there. He bore the shock better; was taken out, rubbed, and put to bed. Slept better; the tongue appeared cleaner, and he was not so violent. Bowels open; he begged to be released from confinement, which was complied with. He took a little exercise; we put him in the shower-bath almost without any difficulty; sleep returned; gave him a dose of calomel and colocynth; more rational; he inquired what had been the matter; thought he had been asleep, and in the evening begged himself to go into the bath and have more medicine. From that time he became tranquil, took mild aperients, and was discharged well in a fortnight from the date of his admission."

"We have had several cases, nearly of the same nature, where the shower-bath in its results proved invaluable."

It is clear, therefore, from this statement, that it is to cases of dementia that it is applicable. I am not aware whether the douche is much employed in this country; in the houses where I have inquired, I believe not. Pinel speaks of it in high terms; and the power of graduation, so as not to give too violent a shock, allows of its employment in private.

The patient is put into the shower-bath, and I give the detail of the process in the words of the author himself, M. Pinel:—

"A happy combination of the douche with the bath adds greatly to its efficacy, and prevents even the smallest inconvenience which might arise from it. To each bath, and directly over the head of the maniac, is adapted a tube, so constructed as to let water fall three feet in height; the stream of water being proportioned to the end proposed, and graduated according to the symptoms, but in general the stream is very small. It is not until nearly the end of the bath, and during a few minutes, that the douche is administered; when the circulation of the blood has been drawn to the surface of the body, and is to be diminished towards the head by the cold produced. The douche is omitted as the disease begins to decline and during the convalescence, but is resumed at the approach of an accession of mania, or when it has already broken forth. If the appearance of excitement be very moderate, the practice is confined to letting, drop by drop, cold water fall upon the head, which determines a moderate degree of cold, both by the impression of the liquid and the evaporation which takes place."

The cold plunging bath, formerly so much recommended by Van Helmont, and in which the patient was half drowned, in the hope that this short interval between life and death would put an end to the chain of perverted ideas, and that, with new life, the patient would recover new senses, is, as it would ap-

pear, not now employed, at least in this country.

As the use of cold in various forms appears to be productive, under proper management, of the greatest advantage in cases of mania, a corresponding good effect has been said often to be observed in the employment of the warm bath in cases of melancholia. I was informed at Charenton, in France, and the Quakers' retreat, near York, that more marked advantage was derived from the employment of the warm bath in cases of melancholy than from any known remedy in diseases of the mind; and Mr. Tuke states this opinion before the Committee of the House of Commons:—"The warm bath (he says) is used more medicinally than the cold bath; and it has been observed that the warm bath has been found very beneficial, particularly in female cases." Dr. Guislain gives his very important testimony to the benefit of it, especially in cases where lunatics refuse nourishment. Like all other remedies, it is probably often of benefit, and occasionally fails. It appears likely to be more frequently advantageous when employed among foreigners, because from infancy warm baths are used, both as remedies and luxuries, and in either view may become more necessary than to persons who have never been in the habit of employing them.

Producing discharges from the scalp by means of blistering substances or escharotics, have been strongly recommended in chronic cases, both of mania and melancholy; and one of the greatest names which ever adorned the profession of physic has been brought forward in approbation of this practice. Dr. Jenner believed that he had cured cases of insanity by producing pustules on the scalp. A case was related to me, on good authority, where mania after continued fever was cured by this means twice repeated, the symptoms of mania entirely disappearing with the second crop of pustules. I have, of course, endeavoured to inquire whether such beneficial effects are at all frequent. "We have given this a trial, (say Messrs. Beverley and Philips) more particularly the tartar emetic ointment, and with, we thought, some advantage, in a few cases, but we found, from the constant restlessness of the patient, erysipelas came on from the friction against the pillow, so that we were obliged to abandon it. We afterwards tried it in several cases over the biceps humeri muscle with, I think, more benefit than on the head: these were cases of a very violent nature, stout robust habits, and who were, for the most part, subject to periodical attacks. The use of it had evidently the effect of making the paroxysms of much shorter duration. We have also used blisters to the inside of the thighs, and calves of the legs, with advantage." The employment of tartar emetic

internally may be directed on two principles, either to diminish the action of the heart and arteries, where these are excited by keeping the patient in a constant state of nausea; secondly, as an emetic in melancholy, where full and repeated vomiting is of great service in producing a more rapid circulation in the vessels of the abdomen, and relieving the viscera, already gorged with blood. The former application of the remedy appears most applicable to mania; the second to monomania, or melancholy. "Tartar emetic, in doses of one or two grains, given internally every hour, is worth noticing in patients who are subject to violent paroxysms, particularly those who have increased vascular excitement, with great restlessness. The patient generally complains of nausea without vomiting, becomes languid and quiet, rests better, appetite improves, and in a few days is trusted out of confinement."

In addition to these means of diminishing sensibility and irritability, others have been sought for from the class of sedative medicine, and of course from the use of the greatest blessing ever accorded to mankind—opium. The opinions with regard to the use of opium in mania are very various, but may, I think, easily be explained. Where vascular excitement exists, together with increased sensibility of the brain, the restlessness is increased by the administration of opium; where perverted perception arises from disorder of the functions of the abdominal viscera, the constipating effect of this medicine, and the manner in which it acts to diminish all the secretions, obviously renders it hurtful; and it must be added, that in some constitutions it is poison. Hence it is far from generally useful even in the cases in which it is indicated; and as it is often the case that physicians neglect medicines (after a time) which do not entirely fulfil their expectations, so occasionally this medicine has been unduly estimated, and immediately afterwards, as improperly neglected. In some instances mistaken pathology has lent its aid to undervalue the medicine, and one is forced occasionally to listen to theoretic doubts about its efficacy in cases of great and urgent irritability from the prevalent opinion that all disease arises from inflammation, acute or subacute, and the corresponding error that opium necessarily occasions congestion in the brain. There is no question that where opium is not contra-indicated from peculiarity in the individual, or the presence of another disease to which it is ill-adapted, it is of all others the remedy to diminish the sensibility and irritability of the system, to make the wretched forget his grief, the ruined his poverty, and even the criminal the mental retribution of his wickedness: and in the same way it often removes from the imagination of the

maniac his supposed iniquities. Still partly the real, and partly the theoretical objections to this remedy, have caused physicians to seek for some substitute from the class of sedatives which would exhaust that increased sensibility which magnified a hundred fold the objects presented to it.

It is now some years since the French chemists announced to the world that opium contained two substances on which its peculiar properties depended. Narcotine, believed to possess the stimulant, and an alkaline substance, united with a peculiar acid, existing in opium under the name of meconate of Morphia, the alkaline body, morphia, being believed to possess all the soothing effects of opium without its stimulant properties. The morphia was found to unite in preference with the acetic acid, and under this form of acetate of morphia to be more soluble in water. It is remarkable that the combination of opium with vinegar has been particularly approved of by the celebrated Van Swieten* for the cure of this disease, and that vinegar, for what reason I cannot discover, has been considered very efficacious in the treatment of mania. Since the discovery of the French chemists, morphia has been much employed; and if I may believe my own observation, and that of persons of very extensive experience in maniacal diseases, with most complete success. I have repeatedly administered it in disease where opium was ineffectual from the headache and vomiting which accompanied its use, with the most decided benefit. I subjoin the following case, which recently occurred, and which proves the benefit of this medicine:—

A gentleman was attacked, some weeks after a most severe cough and cold, with great difficulty of breathing, attended with the impossibility of lying down at night, together with intermitting pulse and swellings of the legs, the heart and great vessels having become enlarged and dilated after the inflammation. The principal inconvenience in this case arose from the want of sleep, the patient never having been able to lie down during twenty-two nights. Opium, of course, was resorted to, and in very large doses, but the distress produced was so great that the patient preferred his sleepless nights to the dreams and scanty rest produced by this means. The patient came to London, and I recommended him the acetate of morphia, in the dose of three-quarters of a grain. He slept well, and has repeated the medicine for several weeks without its having once failed of the most complete success.

But it is to the subject of mania that this

applies, and I have it in my power to lay before the College the most convincing proof of the efficacy of this medicine, an efficacy which in my mind renders it invaluable, and which I should not venture to praise so strongly had it not been corroborated by the extensive experience of the gentleman alluded to.

“We have found the acetate of morphia useful, both in the excited and the low form of insanity. We have also found it useful in cases of fixed delusions, but not of any great standing, and more useful in the low than the excited form of the disease. Of five cases of melancholy, three got well; the remaining two are certainly improving under the use of this medicine. Of five cases of excitement, two were discharged cured; one remains much improved; two received no benefit. It is necessary to observe that we have used this medicine in several cases without taking notes, and the result was similar to the two cases mentioned, that is, without benefit. It appeared to us that morphia did not produce the same good effect in excited as in other cases, unless there was an occasional interval of reason. In the cases mentioned we have commenced with a fourth, and have not found it necessary to exceed half a grain. At present we have a patient taking half a grain dose every night with decided advantage, and we think the case very interesting, and proving the extraordinary effect of this medicine in cases of melancholy. A woman, of the age of 36, the mother of four children, was attacked with depression of spirits while pregnant of her last child. She did not feel the attack before she quickened, but immediately after she had a strong desire to destroy herself and children. This continued during pregnancy. After she was delivered she became worse, and attempted to commit suicide several times, and described her feelings, which is not common in such cases. She continued in this state, not fit to be trusted without a strict watch. She was sent here about two years ago; and what is extraordinary in her case is, that about noon all the feelings of desire of self-destruction left her. This occurred within the last three months, from which time they have remained the whole of the day. Various means were tried without effect. Our first idea, from the regularity of the attack was, to treat her as an intermittent, which failed. About a fortnight ago we gave her the morphia, beginning with a fourth of a grain, and gradually increasing it to half a grain; after taking the second dose, one-third of a grain. She slept all night; in the morning was cheerful, without feeling the propensity to destroy herself. The third day she had a return, which lasted until noon; the dose was then increased to half a grain. The fourth morning she had not any return, and continued well until

* Van Swieten says, that an accidental case first brought into notice the efficacy of this combination. A girl, who was maniacal, swallowed by mistake a scruple of opium mixed with vinegar: this mistake produced her cure.

the fifth day after the half-grain dose was given, when she had a return from five o'clock in the morning until nine, a paroxysm three hours shorter than any of the preceding. She is now free from any feeling to destroy herself.

"The following is a case of the excited kind, in which this remedy was employed with advantage.

"A. R. æt. 36, was admitted in February 1831, in a very high state of nervous excitement; she was a widow, and mother of four children. When admitted she was much excited, and constantly talking. Tongue dry; pulse very quick; skin moist. She was excited to such a degree that she tore the jacket and clothes to ribbons; refused her food; and would swallow nothing without force. She was ordered a pint of porter daily, with beef-tea and arrow-root. This diet was considered necessary, because if so much excitement continued without support she would fall into a state of collapse, and die. All our efforts being unavailing in giving her food, we determined to try the morphia. The first night it had not the least effect; she was noisy, screaming until morning; on the following day refused her food, and the excitement was unabated; we got the porter and arrow-root swallowed with some difficulty; the morphia was increased to half a grain; did not make any noise during the night, and appeared to be drowsy in the morning; but when she was spoken to answered in a very incoherent way, and the excitement continued; the porter and beef-tea was given with less trouble; the medicine repeated; slept well during the night; appeared, on questioning her in the morning, to have a slight return of reason, such as to inquire where she was; took her food better; tongue moist; pulse not so quick, and bowels open. Ordered two pints of porter, beef-tea, and arrow-root, as usual. Medicine repeated at night; slept very well; more rational; began to cry; took her food much better; drank the porter, and appeared to relish it; the medicine was repeated every night until 6th of March, when she appeared perfectly well; the morphia was discontinued; she employed herself, and was discharged 14th April cured."

The extract of the *hyoscyamus niger*, given in full doses, enjoys likewise on the continent of Europe a great reputation: it is the sedative which is preferred, and the fact of its being a mild purgative, has caused its employment by many practitioners in this country. It is believed to be less stimulating than opium; perhaps it is so; I am sure it is far less effectual as a sedative. The only English physician of great reputation who has spoken of its efficacy in diminishing the excitement of the brain in mania is Dr. Fothergill, who was of opinion he had cured puerperal insanity by this medicine; the

dose was five grains, three or four times daily.

The most powerful of all the class of vegetable sedatives is undoubtedly the belladonna. It is not to be wondered at, therefore, that it has been recommended for diminishing the sensibility and irritability of the brain in mania: it is not an opiate, but diminishes pain. This is the best explanation I can give of its effect. I have used it extensively in St. George's Hospital; and, as far as my practice would permit, in private life, and often with the most marked good effect. The following is one of the cases in which its alleviating powers were most marked:—A general officer was attacked, about fourteen years ago, with the painful affection of the second branch of the fifth pair of nerves—*tic douloureux*. He underwent various remedies from the recommendation of the most celebrated physicians in London. The disease yielded to very large doses of belladonna, and it never reappeared for ten years. At the expiration of this time he had an apoplectic seizure, which left him paralytic of the right side, very imperfect condition of speech, and frequent convulsive and painful affections of the nerves, sometimes choking, and other times startings of the nerves of the affected limb, and occasionally the return of the *tic douloureux*. It is impossible to conceive more acute pain than is experienced by the patient at these times. He always (and I have witnessed at least ten such paroxysms) finds relief in the extract of belladonna. Half a grain is administered every four hours; and always by the time the third dose has had time to operate, the pains and spasmodic twitches disappear. It might be supposed that the pain terminated of itself, or that the spasmodic affection ceased naturally at this time; but distressed at the weak state in which the belladonna leaves him, the patient has once or twice refused to take it, and he has suffered intense pain much longer than he otherwise would have done, being obliged to resort to the remedy at last.

Gréding speaks highly of this medicine in epilepsy; and in one or two cases in the hospital it has appeared to have rendered the intervals much longer, but I cannot lay claim to a single cure. It appears to me well worth the trial of physicians in mania, especially that which arises from moral causes, and is attended with pain and increased sensibility of the brain.

Various other substances from the class of sedatives have been adopted and relinquished alternately. The most powerful sedative with which I am acquainted—hydrocyanic acid, has not, I believe, been used in this country. The unhappy consequences which followed its exhibition in Paris would deter physicians from any but the most cautious experiments with this medicine. It is, how-

ever, in my opinion, from this class of medicines that the greatest improvement will be derived in the treatment of disease of the mind. It requires that practical physicians should turn their attention to it; first discarding the idea which is hostile to all improvement—either that mania is incurable, or that it always, or even most frequently, depends on organic disease of the brain.

There is another powerful medicine whose efficacy cannot be explained in our present state of science—arsenic. It appears to alter the sensibility and irritability of the brain, and has long been known as very efficacious in intermittent diseases. I have used it several times, with great benefit, in cases of chronic pain in the head, trembling and sleeplessness, nearly allied to mania. A woman, *æt.* 40, (servant to a lady in the Regent's Park,) was attacked with constant pain in the head, confusion, and giddiness, attended at times with loud noises, which she described like breaking stones; at other times images presented themselves to her mind, and her nights were entirely sleepless; pulse quick and weak. This condition continued for months, during which time I employed every means in my power for her relief; at length I resorted to the employment of arsenic. The patient took ten minims of the liquor arsenicalis twice daily, subsequently increased to the same quantity three times in the day. In about a week very great improvement had taken place; the pains had diminished, and the nights were tranquil. In a fortnight her ailments entirely left her.

The next was the case of John Graham, *æt.* 30, admitted into St. George's Hospital, under my care, November 24th, 1830. The report on admission was as follows:—Ill since June last with pain in the forehead, diverging to each side, very excruciating; and reported to feel as if the head was forced or burst open. The pains are worse at night, so as entirely to prevent sleep. The pupils are dilated and the conjunctivæ injected with blood; sense of smell increased in acuteness; bowels constipated; pulse 100, very weak; skin cold.

The bowels were ordered to be kept open, and sedative and antispasmodic medicines were employed without effect; on the 6th of December he was ordered five minims of liquor arsenicalis twice in the day.

11th.—The pains were reported greatly relieved.

13th.—The pupils contracted naturally; the pain and pressure in the head nearly gone, except when he lies down.

16th.—The medicine increased to five minims thrice daily: from this time the pains entirely disappeared. He remained in the house a fortnight, to see if any relapse took place, when he was dismissed free from ailment.

It has occurred to me to see several

similar cases; but these, perhaps, are as good examples as I could select, of this peculiar effect in the medicine; and I cannot but think it might, in proper hands, be very beneficially employed in some maniacal cases. Although I am quite aware that this medicine is similarly employed by many physicians in practice, yet I cannot learn that it has hitherto been tried in any of the numerous similar, and more severe cases, which are found in lunatic asylums.

In female cases, and especially those kinds which approach nearest to hysteria, the fætid gums and antispasmodic medicines have been principally used, and there can be no doubt that such means may tend very materially, by proper administration, towards a cure; but of all the diffusible stimulants which have been recommended, camphor has had a peculiar reputation. This was the remedy on which Dr. Perfect relied in the treatment of numerous cases of insanity. In 103 cases he conceives the patient derived essential benefit from it, and he administered it in the solid form. The following is one of these cases:—

Mrs. S. B., a married woman, became melancholic. Her complexion was pale, eyes red, tongue dry, pulse small, hard, and irregular. After bleeding and vomiting, Dr. Perfect ordered two scruples of camphor to be taken morning and evening. An eruption came out after this treatment all over the body. The catamenia returned; nitre was added to the camphor, and the patient recovered completely.

Purgative medicines have been from all antiquity greatly praised in the treatment, and above all the helleborus niger. In our present state of knowledge there are many purgative medicines far preferable to this, although it is consecrated by centuries of experience. Moderate, and frequently-repeated purging appear, as far as I can collect, to be very useful in monomania. One of the most advantageous discoveries in the modern art of medicine, has been the oil of croton, because there is scarcely any condition in which it cannot be administered, and very large doses of other medicines are required to fulfil the indication. I have repeatedly had occasion to administer this medicine in diseases of the brain, after blood-letting, in acute cases and in chronic cases, alternately with sedatives, and with the greatest possible good effect. Dr. Abercromby affords likewise his powerful testimony in favour of the derivative, as well as purgative, effects of this medicine. A drop may advantageously be administered in a little jelly, which covers the acrid taste; when made into pills it appears to lose partially its beneficial effects. Messrs. Beverley and Phillips have afforded me the following information on the curative treatment by purgatives:—“Purgatives are, we think, of the

greatest importance. We have not tried long courses of drastic purgatives; we have tried courses of mild purgatives in melancholy with advantage. There appears almost always a want of energy in the constitution of melancholic patients; the circulation is languid; the absorbent system sluggish; there is a furred tongue and swelling of the legs,—in those cases we have found a course of laxative medicine, with gentle exercise, of great service. The exercise is generally enforced, as they will not comply without it, frequently requiring two assistants to take them by the arms, and oblige them to walk. The patient's health by this means improves, and the mind by other medicine, particularly the morphia, which we have given at this period with advantage."

The *oleum terebinthinæ*, a medicine combining purgative, anti-spasmodic, and stimulant properties, has been much employed in cases of hysteria, connected with epilepsy; it has been recommended by Dr. Latham, senior, Dr. Thomas Young, and Dr. Percival; and in the latter cases especially, by Dr. Prichard, of Bristol. Nevertheless, it has never become an ordinary practice. I lately had the opportunity of seeing very decided effects from it, in a case—an out-patient of St. George's Hospital, æt. 15. The patient had never menstruated, and was in a state very nearly approaching to idiocy, being unable to speak or take notice, except occasionally when struck with the appearance of some glittering ornament, when she expressed her surprise by remarkable and violent gestures. The pulse was quick and weak; great pain in the head; skin cold. She was ordered two drachms of *ol. terebinth.* and the same quantity of castor oil every morning, and in about a fortnight she recovered the use of her senses; but she remains in a weakly state of body, and the catamenia have not occurred. She is now able to take steel. I am inclined to think that great benefit may be derived from the employment of this medicine in similar cases, and such are not very uncommon.

The belief that cases of insanity always depend on organic causes, or a state of acute or subacute inflammation of the brain, has not only led to the erroneous treatment of many of these forms of disease, by venesection, but has suggested an antiphlogistic diet. We have, I think, the best evidence from the greatest experience in France and England, of the evil consequent on such practice. M. Pinel draws a terrible picture of the afflicting consequences of the short allowance on which the patients of the Bicêtre were placed in 1796; and it has been seen that a full diet, and even considerable quantities of stimulants, are often productive of the utmost advantage in what are termed high cases. In the cases arising

from child-bed, or during nursing, Dr. Gooch has very clearly demonstrated that these occur either in consequence of, or during, an exhausting process, and are relieved by tonic and antispasmodic medicines and restorative diet.

I have now spoken cursorily of the principal means of cure, from medicine, which may be adapted to mental disease; any improvement in treatment, and consequently any collection of facts, to serve as guides to future observers, must obviously depend on the judgment exercised in discriminating the causes, both moral and physical. The small bleedings, for instance, which would be useful in mania depending on chronic disease of the heart, and steatomatous or bony depositions in the smaller arteries of the brain, would be a fatal error in those frequent cases connected with hysteria; and the large evacuations and antiphlogistic treatment imperatively called for in inflammation of the membranes of the brain, would change mania into furious madness, by increasing the already excited morbid sensibility of the brain and nervous system. I hope, little as I have been able to say upon these subjects, that it is enough to prove that it is to the educated physician, to the man who is engaged in the constant discharge of the duties of his profession, that such cases should be made a subject of deep importance; that all his experience should be brought to bear; that all his faculties and observation should be concentrated in improving this portion of the medical art; not by studying it exclusively, but in conjunction with the other diseases of the human body, and thus removing a great source of quackery and imposture. The educated physician is too often called upon to stand between the public and its prejudices: this must be done, not by deserting our colours, but by shewing that, with every desire to serve the public, neither rewards nor honours, nor fleeting popularity, can make us lend our countenance even to innocent imposture; and that that independence which is the distinguishing mark of an honourable profession, will support us through difficulties, and vindicate the integrity with which we practise that profession. If we carefully investigate disease, and neither resign that interesting and useful study to artful and designing persons, nor suffer ourselves to be overcome by the momentary prejudices of the world; all experience has shewn that medical practitioners so acting have received, and will continue to receive, the respect and homage of society.

CASE OF EPHIDROSIS IDIOPATHICA.

To the Editor of the London Medical Gazette.

SIR,

I know not whether the opinion is founded in correct observation, but I am disposed to believe that there is something very peculiar in the constitution of the present year—every variety of disease appears to present unusual phenomena. Fevers, if inflammatory, quickly assume the typhoid character; or from their commencement give strong evidence of their malignant tendency. The active stage of inflammatory diseases appears to pass as a shadow, and the disturbance which a mere attack of diarrhoea will produce in the vascular and nervous systems but ill accords with the usual and observed effects of that disease. How far these circumstances may be associated with the pestilential state of atmosphere, which at present is depopulating many parts of Europe, it may be difficult to decide, and it remains a point of no trifling moment for our consideration whether these phenomena are to be considered as precursors of future and more fatal mischief, or are to be regarded as modifications of the same calamity. With such impressions, it is to be supposed that every unusual occurrence will be adduced in support of the belief; nor can I think that the following case, which I offer for insertion in your journal, in any way contradicts the opinion.

A lady, whose mind and body had been harassed by unremitted attendance on a sick and valued relative until his death, through the day subsequent to that event was troubled with repeated attacks of cramp in the legs, and with general feelings of indisposition. Soon after going to bed she was seized with rigor. No perceptible hot stage followed this state of collapse; but a most profuse perspiration within the space of half an hour covered the whole body; her back and limbs became painful, with pulsating pains in the head. I saw her for the first time (later than I intended) the evening subsequent to the attack. The pulse was ranging at 130; the countenance very anxious; the perspiration literally pouring

from the face, the skin of which was exquisitely tender (and still remains so) from the constant use of the handkerchief; and it had been necessary to keep a napkin under the chin to receive the perspiration as it ran down the face; every part of her body was in the same state; she had had no sleep: there was great sense of weakness in the abdomen, with unusual and most distressing flatulency. I ordered the following medicines, directing that she should be kept moderately cool, and no warm fluids to be given.

R Confect. Arom. ʒss.

Tr. Hyos. ʒss.

Sp. Ether, Nit. ʒss.

Tr. Card. c. ʒj.

Aq. Puræ, ʒx. M. fiat haust. stat. sumend et post hor. quatuor repet.

Early the next morning I found her with the pulse reduced to 100 beats in the minute; the perspiration had considerably decreased since four o'clock in the morning, though up to which time it had continued with unabated violence; head still painful; great uneasiness in the back; the flatulent state of abdomen greatly relieved.

R Extract Conii, gr. xvj.

Tr. Cardam. comp. ʒss.

Inf. Rosæ, ʒiij.

Aq. Cinn. ʒiiss. M. fiat. mist. cujus. capt. 4tam part. 4tis horis.

In the evening I found her with the skin in a natural state; pulse 80; no pain in the head or back, but excessively weak. I continued the sedative, and ordered a mild aperient for the morning. On my next visit I found she had passed a comfortable night; skin in a natural state; pulse regular; I continued the sedative every six hours. Two days subsequent to this visit she complained of nothing but debility.

I remain, sir,

Your obedient servant,

HENRY GEORGE.

22, Lower Phillimore-Place,
Kensington, Oct. 21st.

CHOLERA TREATED WITH CAJEPUT OIL.

To the Editor of the London Medical Gazette.

SIR,

If you consider the following case of English cholera, which was clearly at-

tributable to improper ingesta, and in which the oil of cajeput was administered externally and internally, with apparent benefit, sufficiently interesting for insertion in your journal, it is at your service.

I remain, yours, &c.

R. R. ROBINSON,
Surgeon.

13, Cooper's Row, Trinity Square,
October 24, 1831.

N. Brennan, æt. 60, a thin and feeble man, of bad constitution, and rather intemperate habits, who had been sometimes subject to mucous diarrhœa, was purged more than usual on the 13th September, notwithstanding which he eat pork sausages for dinner, and drank porter at 2 p. m. and at 11 p. m. took a pint of ale, and went to bed, as he thought well, about 12. He awoke, however, about two the following morning, with violent cramps in calves of both legs, vomited frequently, and was purged three times. The pain increasing, I was sent for between five and six: he was then suffering severely from cramps in legs; he was very languid, his countenance anxious; there was no pain in abdomen, where he could bear to be pressed; skin warm and perspiring, tongue coated, great thirst, pulse soft and regular, between 80 and 90.

Pulv. Rhei gr. xxv. Pulv. Cinnam. co. gr. v. statim. Applicentur frictions crucibus.

12, noon. — Contrary to orders, he had taken port wine and water; had been constantly sick; the fluid vomited appeared to consist chiefly of mucous tinged by the wine; cramps have been frequent and severe, but have always been diminished in duration by friction.

Cal. gr. iij. Opii gr. j. statim.

6, p. m. — Constantly sick; no motion; cramps frequent and severe.

Ol. Cajeput. gtts. xxx. Tinct. Opii gtts. xv. statim ss. The same to be used as an embrocation.

10, p. m. — The cajeput immediately returned, and he has been constantly sick since; has vomited altogether since last report about $\frac{3}{4}$ of clay-coloured fluid, strongly impregnated with the oil; cramps, which before invariably followed each attempt to vomit, have occurred only five times since last report, and have not been so severe; thirst

great, tongue much furred, skin warm and perspiring, pulse soft, 90; no motion.

Pulv. Opii gr. j. — Repetatur Linim.

Sept. 15th. — Slept well, but little vomiting; cramps occasionally on moving, not otherwise; less thirst; urine scanty, but high coloured; tongue coated; pulse soft, regular, 84.

Ol. Ricini $\frac{3}{4}$ ss. statim.

16th. — Cramps gone; sick only once; two motions; tongue still coated; some thirst.

Cal. gr. j. Ext. Colocynth co. gr. v. o. n.
Ol. Ricin. $\frac{3}{4}$ ss. p. mane.

18th. — Up, and convalescent; sickness and cramps gone; tongue clean; bowels open.

Inf. Gent. co. $\frac{3}{4}$ ss. Mag. Sulph. $\frac{3}{4}$ ss. bis die.

20th. — Recovered his strength rapidly, and has had no return.

REMARKS. — The spasms appeared in this case to be chiefly relieved by the outward application of cajeput and laudanum as an embrocation, which I am not aware has been hitherto used in cholera.

OPIUM IN CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

It appears to me to be generally the practice to give opium in a very wrong form in cases of cholera; and as the public is at the present time under so great an apprehension of this dreadful disease coming to this country, I think it my duty to ask, whether it would not be much better to give it in its hard purified state, or to administer the acetate of morphia, for it is well known that light, according to the experiments of Vogel, has the power of decomposing the tincture, and I make no doubt that it is the common practice for the druggists to adulterate the powder. Should you think the above observations worthy of notice in your valuable Gazette, you will oblige me by inserting them.

I remain,

Your obedient humble servant,
JOHN GREENING, Surgeon.

Worcester, Bridge-Street,
Oct. 24th, 1831.

YELLOW GUM, OR GRASS TREE, OF
NEW SOUTH WALES (XANTHOR-
RHŒA.)

ANALYSES & NOTICES OF BOOKS.

THE Xanthorrhœa, or yellow gum tree, is found abundantly in New South Wales, where, among the colonists, it is named the grass tree, from its long, pendant, grassy foliage. It is a tree of curious growth, and I have seen some of the species of from eight to ten feet in height. From the centre of the foliage rises the straight flowering stem, which is frequently ten feet and upwards in length; it is round and very light, combining lightness and strength; it is used by the natives for making their spears, fish-gigs, &c. The scape terminates in a cylindrical spike; the flowers are white, small, and numerous; an albumen is secreted from them, which is greedily devoured by the natives, and numerous birds; it is said to be very agreeable to the taste. The capsules are triangular, and contain three flat, black seeds, in distinct cells.

It derives its name, "Yellow gum tree," from secreting a gum-resin of a bright yellow colour, and resembling in appearance the resin of the Stalagnitis Cambogioides, or gamboge tree. Externally the yellow gum has a dull appearance, but breaks with a shining bright yellow fracture, and is sometimes streaked internally with red. The resin is soluble in spirits of wine, but is insoluble in water; it is light and brittle, and is, in its natural state, without any fragrant smell; but by the action of fire it yields an aromatic odour, resembling the frankincense, for which it might be used as a substitute. It exudes spontaneously from the trunk, but only in very small globules; yet it may be melted into large masses. At the base of the tree are congeries of scales, between which the gum is found conereted in small pieces. One tree yields a considerable quantity of the gum.

This resin (more commonly known as the gum acaroides) is slightly bitter, pungent, and astringent, and has been used in dyspeptic, dysenteric, and other cases; but not, I believe, with such success as to cause it to be admitted into our materia medica.—*Mr. G. Bennett's MS. Journal.*

London, Sep 1. 27, 1831.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Essays on the Effects of Iodine in Scrofulous Diseases; including an Inquiry into the Mode of preparing Ioduretted Baths. Translated from the French of M. LUGOL, Physician to the Hôpital St. Louis, by W. B. O'SHAUGHNESSY, M.D. With an Appendix by the Translator.

THIS volume consists of a translation of three Essays published by M. Lugol, physician to the Hôpital St. Louis, of Paris; followed by an Appendix by Dr. O'Shaughnessy, containing some important additional information, which we shall lay before our readers in the sequel. Of the opinion entertained in France of these papers, some idea may be gathered from the circumstance of their having received the warm eulogies of the reporters appointed by the Académie Royale, as well as the unanimous approbation of the medical press—to say nothing of six thousand francs voted to the author by the Institute. The intelligent translator of M. Lugol's Essays attributes much of the success attending the use of iodine at the St. Louis, to the care, skill, and patience of the physician—to the period of treating the cases being unfettered by the limits as to time, which prevent investigations of this nature from being satisfactorily conducted in the hospitals of this country. The cases, indeed, are numerous and astonishing—so much so, that farther trials will be required before practitioners can become convinced that similar success, in scrofula especially, is to be hoped for among us.

M. Lugol seems to be a person of eccentric manners, and an enthusiast, affecting in his discourses the most preposterous forms of expression. Thus we are informed that he will sometimes personify his favourite medicine, and exclaim, "*O iode, iode, O mon fils! pourra-t-il se rencontrer jamais une langue capable de célébrer dignement tes vertus anti-scrofulenses!*" And again, on pointing to a patient in whom the iodine had, in his estimation, gained a great triumph over the disease, "*Voici la bataille d'Austerlitz de l'iode!*"—

Our Gallic neighbours may, indeed, say of this high-flown style—

Ce style figuré dont on fait vanité,
Sort du bon caractère et de la vérité—

but to us it seems wretched bathos and downright nonsense. A knowledge of these circumstances leads us to trust more to the report of the commissioners than to the statements of M. Lugol, who, without intending to deceive, may yet mislead. Now the report is really very favourable, and the profession is indebted to Dr. O'Shaughnessy for having given, in so convenient a form, all that is valuable in the observations of the French practitioner.

The preparation of iodine which M. Lugol regarded until lately as most certain, was a solution in distilled water; observing, however, that the vehicle was never carried in quantity much beyond what was necessary in order to obtain a perfect solution; the dose being half a grain to begin with, gradually increased to two-thirds of a grain, and finally a grain, in twenty-four hours. This, it will be perceived, is greatly under the maximum doses of M. Coindet, who gave to the extent of three grains a-day. Indeed our author particularly objects to the tincture so much used by the Swiss physician, which, being administered in an aqueous vehicle, leads to the precipitation of the iodine in the solid form, and thus incurs great risk of serious injury to the stomach. A pound of water was the quantity employed by M. Lugol in making his solutions, and to these he generally added a few (twelve) grains of common salt, or, if we must use the more scientific language of our author, of chloruret of sodium. For external use he employed an ointment, having three degrees of strength: No. 1, containing, in two pounds of fresh lard, hydriodate of potass, $\mathfrak{Z}\text{iv}$. and iodine, $\mathfrak{Z}\text{iv}$. No. 2, hydriodate of potass, $\mathfrak{Z}\text{v}$. and iodine, $\mathfrak{Z}\text{xiv}$.; and No. 3, $\mathfrak{Z}\text{v}$. and $\mathfrak{Z}\text{xvi}$. * Occasionally, as a substitute for these ointments, was used a solution—viz. No. 1, gr. ii. of iodine, gr. iv. of hydrod. of potass, to lbj . of water; No. 2, gr. iii. and gr. vi. to lbj .; and No. 3, gr. iv. with gr. viii. to lbj . But upon these modes of exhibition, though much superior to

what had been previously used, farther experience enabled M. Lugol to improve, and he has latterly abandoned the simple aqueous solution for one made by dissolving the iodine in a solution of potass, thus:—

Ioduretted Mineral Water.

“ R No. 1.—Iodine, gr. $\frac{3}{4}$; Hydriodate of potass, gr. $1\frac{1}{2}$; Distilled water, $\mathfrak{Z}\text{viii}$.

No. 2.—Iodine, gr. i.; Hyd. of potass, gr. ij .; distilled water, $\mathfrak{Z}\text{viii}$.

No. 3.—Iodine, gr. $1\frac{1}{4}$; Hyd. of potash, gr. ij . $\frac{1}{2}$; distilled water, $\mathfrak{Z}\text{viii}$.”

This preparation is quite transparent, of a fine orange colour, and keeps for a considerable time; while it is so little disagreeable that children take it readily if mixed with sugar. This addition, however, it is worthy of remark, ought only to be made when it is just about to be administered, as a decomposition results if it be allowed to stand for some hours. Two thirds of No. 1, as above, are to be taken in the course of the day, to begin—and this ought to be continued for a fortnight; after which, the whole of the mixture may be taken daily.

The external effects of iodine, when applied to ulcers, were greatly increased local action, sense of pricking and smarting, which was often prolonged. In a few days followed an improvement in the aspect of the sores, with or without suppuration. The local action generally lessens in activity as the surfaces heal, but in rare cases it continues, however long it may be used, to produce undiminished excitation.

The internal effects of iodine vary: one of the best, though not one of the most common, is that of increasing the appetite to a great degree. A more general consequence of its use is an increase in the urinary secretion: sometimes the diuresis is very considerable indeed. More than one person in three is purged by it, and in some this is attended with colic. In several cases it produced salivation. Some patients, particularly females, complained of it producing pain of the stomach; and when this happened, the inconvenience was removed by administering two or three ounces of the kina wine after the mineral water.

Such are the principal forms of exhibiting iodine, as adopted by M. Lugol;

* No. 1, made up in smaller quantity, and with rather less iodine, may be prescribed thus:

Iodine, gr. xiii.; Hydriod. of Potass, iv . scruples; fresh lard, ii . ounces. M.

and we shall conclude our notice of his part of the volume by quoting a portion of the Report upon the subject, by MM. Serres, Magendie, and Dumeril.

"The author of the Memoir has carefully noticed the effects produced by the iodine on the animal economy. Applied externally, its local action has always been very sensible: it determines on the surfaces of the ulcers a feeling of smarting, accompanied with painful itchings. *This application to the diseased surfaces changes their appearance, and frequently produces as appreciable an effect as that determined by mercury on venereal ulcers.* Moreover, the mode of its action does not appear to be invariably the same: sometimes the iodine seems to melt down and resolve the tubercles, sometimes, on the contrary, it urges them on to rapid suppuration. At other times the painful sensation appears to diminish in proportion to the healing of the surfaces, an effect which is perhaps dependent on habit; nevertheless, some ulcers remain sensible while the curative process is not at all established.

"Internally administered, and always in small doses, and with the most prudent slowness, the ioduretted water constantly excites the appetite, and appears to increase the urinary and salivary secretions. Sometimes, but very rarely, it has become purgative to so considerable an extent that its use was necessarily suspended, at different intervals, from two to three days each. In other and still rarer cases, in which the solution of iodine appeared to occasion pain in the stomach, the wine of quinquina, given according to the directions of M. Coindet, in a dose of two or three ounces, put an end to the troublesome symptoms. M. Lugol, however, always declined, as much as possible, this association of remedies, in order to avoid complexity in the results of his treatment.

"Iodine, administered in this diluted form, has never caused emaciation nor produced the expectoration of blood or other accidents, which many have imputed to its action.

"From the contents of the first Memoir, it appears that M. Lugol has treated with iodine alone, in seventeen months, at the Hôpital St. Louis, 109 scrofulous patients, of which sixty-one were males and forty-eight females.

"That at the close of last year, thirty-

nine (twenty-nine males, ten females) were still under treatment.

"That thirty (seventeen males, thirteen females) had quitted the hospital with marked improvement.

"That in four cases (two males, two females) the treatment was ineffectual.

"Finally, that thirty-six (thirteen males, twenty-three females) were discharged completely cured.

"The author concludes, from all the facts he has collected, and the researches he has conducted, that iodine deserves to be considered as the most efficacious remedy in scrofulous diseases, since it has constantly arrested their progress, or at least exercised a salutary action in the treatment of all tubercular tumors, even when it has not evidently accomplished their cure. He therefore believes that the introduction of this remedy into medicine is one of the most valuable acquisitions the healing art has made in modern times.

"We shall then confine ourselves to say, that after having made ourselves acquainted with the facts cited in the memoir, we have been enabled to confirm the evident action of the remedy; and that we believe M. Lugol to have effected a work of great utility by availing himself of the facilities afforded by his situation, in seeking for a remedy for a disease hitherto so deplorable and desperate. We consequently propose to the Academy to encourage this physician to persevere in the researches which he has hitherto pursued with so much zeal and sagacity."

An appendix by the translator contains some farther evidence in favour of iodine, from the practice of various other physicians and surgeons in France; but the part of it which appears to us most valuable is the author's own, namely, a clear and succinct account of the chemical properties of iodine and hydriodate of potass, with their adulterations, &c.

"*Adulterations, &c. of Iodine.* — From the high price at which iodine was sold on its first introduction into medicine, a great inducement was afforded for its adulteration, and accordingly, with a clumsiness and ignorance only equalled by their shameful cupidity, some druggists were in the habit of mixing the iodine with a liberal per-centage of charcoal, the protoxide of iron, plumbago, or the carburet of that metal.

"Although the price of the article has now fallen to 1s 6d. the ounce, with many eminent and honourable wholesale houses, still, perhaps, from the difficulty of abandoning old habits, some dealers yet practise the admixture above-mentioned. The fraud may be at once discovered by heating ten grains (accurately weighed) of the suspected sample in a glass tube by a spirit lamp, and continuing the heat till no violet vapour is evolved; if any residuum remain, it indicates an adulteration, the extent of which may be ascertained by the weight of the fixed matter.

"Perhaps an easier process is by throwing the suspected specimen into strong alcohol in sufficient quantity. All the foreign ingredients above enumerated remain undissolved.

"By either of these methods the mixture of charcoal, the protoxide of iron, or the carburet of iron, may be discovered. I should not omit to add, that I have met with one specimen much more artfully and scientifically adulterated, and in which the fraudulent ingredients were, at the same time, soluble in alcohol, and volatilised by heat. I forbear, however, alluding to this mixture more minutely, because the fraud is comparatively so difficult of detection, that describing it would, perhaps, only lead to its more general practice. I should add, that in the last edition of Gray's Supplement to the Pharmacopœias, the editor states that iodine is sold at the absurdly extravagant price of 1l. 5s. per ounce."

"Adulteration of Hydriodate of Potash.—The falsifications of this salt are so extensive and peculiar that the practitioner, who is not aware of their existence and the mode of their detec-

tion, need never attempt to place a patient under Lugol's treatment with any reasonable prospect of success. Had the adulterations been contrived for the sole and express purpose of destroying any anti-scorfulous virtues which iodine may possess, the method could not have been more ingeniously devised.

"It was long known that hydriodate of potash was apt, during its preparation, according to the method of boiling with the alkali, to be mixed with a slight excess of potash, probably from the weakness of the spirit used to dissolve away the hydriodate from the iodate. Little attention, however, was paid to the subject until Mr. Pereira published a paper in the London Medical and Physical Journal, in which he described additional adulterations of much moment. A short time before Mr. Pereira's paper appeared, I had observed the same facts in Scotland, and demonstrated them to my pupils.

"From these conjoint observations it appears that much of the hydriodate of potash at present vended by druggists, &c. contains large quantities of the muriate of soda, carbonate of potash, traces of the sulphate of soda, and other salts in minute quantities. One specimen of which I made a quantitative analysis, contained 64 per cent. of the carbonates alone; and this examination was fully confirmed by Dr. Cristison, who also investigated the subject.

"The pernicious effects thus exerted on the therapeutical applications of iodine in the internal and external treatment of scrofula, goitre, syphilis, &c. may at once be understood by consulting the subjoined comparative statement of the chemical properties of the pure and impure solutions of this salt.

PURE.

- "1. Dissolves iodine in the cold, forming an active ioduretted dydriodate of potash for internal use.
- "2. When warmed with iodine and diluted with water forms an active bath, which excites powerful local action.
- "3. Affords by double decomposition pure iodurets of lead or mercury for internal or external use.

Conclusion.

When pure, a valuable medicinal and pharmaceutical agent.

IMPURE.

- "1. Does not dissolve iodine in the cold.
- "2. When warmed with free iodine, converts it into the hydriodate of potash, a compound proved by Lugol to be nearly inert as a local or general bath.
- "3. Affords by double decomposition carbonates, chlorides, and sulphates of lead or mercury compounds either inert or opposed in their action to the iodurets of these metals.

Conclusion.

"Impure, possessed of no medicinal or pharmaceutical value whatever.

"In order to detect the presence of the carbonates and muriates of soda, or potash, the best method is to add a solution of the nitrate of silver to a solution of the suspected hydriodate; if impure, a white precipitate of the carbonate, chloride, and ioduret of silver, subsides. Filter, and when dry project the precipitate into ammonia, which dissolves the chloride and carbonate of silver, and the ioduret remains; of this ioduret of silver 220 parts correspond to 137.42 of the hydriodate of potash; the amount of the adulteration can, therefore, be readily ascertained by comparing the weight of the hydriodate of potash corresponding to the ioduret of lead obtained, with that of the weight of the specimen before the experiment.

"As a trial test to detect these adulterations, a little acetate of lead should be added to a solution of the suspected specimen; if impure, a copious *white* precipitate is formed; if pure, the deposit is a fine *yellow* colour of a crystalline texture, and perfectly soluble in hot water, from which it crystallises on cooling in hexagonal scales of a golden splendour.

"I trust I have now said nearly enough to guard the public and the medical practitioner from the mortifying effects of this shameful practice. All M. Lugol's experience has been placed in vain before the community, unless this sophistication be diligently sought for, and its authors efficiently punished*.

"As it is more than probable that the management and preparation of ioduretted baths will fall into the hands of the proprietors of large bathing concerns, it is highly desirable that the patient should possess the means of ascertaining whether the baths are properly prepared—that is, whether they contain free iodine dissolved in pure hydriodate of potash. For this purpose the bather may procure a specimen of the water, and add to it, when cold, a cold solution of starch in excess: if free iodine be present, the blue colour will be produced, and the filtered colourless liquid will yield a *yellow* precipitate with the acetate of lead. As the patient's sensations will be his principal guide to the quantity of free iodine necessary to excite the cutaneous action of the remedy,

I do not feel it necessary to describe here the mode of analysis by which the quantities of the respective ingredients in a given quantity of water may be ascertained. The analysis is, moreover, so complicated that I could scarcely hope to render it intelligible but to practised chemists, who, of course, do not require the information."

A Practical Guide to Operations on the Teeth. To which is prefixed a Historical Sketch of the Rise and Progress of Dental Surgery. By JAMES SNELL, Dentist, Member of the Royal College of Surgeons, &c. &c.

THE first fifty-five pages of this work are devoted to a history of the healing art, rather misplaced, in our humble opinion; but that is matter of taste. "It is idle (says our author) to inquire with whom, or in what country, medicine took its rise;" and we think it is idle to spend the fourth part of a thin volume, which professes to be a "practical guide to operations on the teeth," in discoursing about Confucius, Zoroaster, Hermes Trismegistus, and other, no doubt, very respectable personages, but who have heretofore been little heard of as dentists.

Those of our readers who practise in the department of surgery on which Mr. Snell's essay treats, will find some useful instructions on the mode of extracting teeth, and some strong objections to the plan lately so much recommended of excision, together with a description of some ingenious mechanical contrivances for facilitating the performance of the various operations. The only subjects of more general interest are referred to in the following short quotation on tooth-brushes and tooth-powder.

"The various opinions which are held relative to the shape and texture of brushes, would lead us to suppose that the matter was a much more important one than it really is. There are even patent tooth-brushes. A late author insists upon the necessity of hard brushes, and states that he has tried for some years to do himself all the injury he possibly could by using a hard brush, and finds that he can inflict none. I confess I am not yet acquainted with any necessity for using a hard brush, presuming upon its doing no injury:

* "When the hydriodate of potash is found to be adulterated, Lugol's aqueous solutions (see formula in Part I.) should be used in the internal treatment."

the teeth do not require it. A brush too hard is as useless, from having no elasticity, as a very soft one, from its having no firmness. There is a medium between the two, which should be chosen. A brush for the anterior part of the teeth should have its bristles cut lower in the centre than at each end, so that when looked at sideways, the bristles should form the segment of a large circle, the external row inclining outwards a little. In texture it should be as elastic as is consistent with a proper degree of firmness, where the gums are not diseased and the teeth not loose ; but when these defects exist, a softer brush should be used. Under any circumstances, however, the hairs should not be so soft as to loose their elasticity by use. The brush should be used as much as possible in a perpendicular direction, not as it regards the brush but the teeth. Brushing the gums until they bleed is recommended by a late author. I see no necessity for this rude method of phlebotomizing ; notwithstanding I believe that the moderate use of the brush upon the gums is highly beneficial.

“ As the grinding surfaces of the molar teeth are apt to retain matter in their indentations which might be injurious, a brush rather larger than that above-mentioned should be used for the purpose of cleaning them ; the bristles should be much stronger, although by no means so strong as some which are sold for this purpose, as it is totally impossible that they can act but upon the projecting points of the teeth. The object is to have the bristles of a sufficient length, strength, and elasticity, that their points may insinuate themselves in the little indentations of the grinding surface. A hard brush, with short bristles, such as are sold for this purpose, is consequently altogether unsuitable. The back part of the teeth are best kept clean with a small square brush, with bristles rather long and elastic, and left highest in the centre, the corners of the square being cut off. The handle of the brush should be bent a little below where the bristles terminate. A flat brush also, with one row of bristles, or a pointed one, the bristles being inserted like a camel hair pencil, is useful for inserting between the teeth, to remove as soon as deposited the tartar which, without care, is very apt to accumulate in that situation.

With these brushes, if well chosen as to their shape and texture, the teeth may be kept clean in every part.”

“ Bearing in mind that the use of a tooth-powder is to assist the action of the brush, in taking off any extraneous body which may adhere to the teeth, and for which purpose the brush alone is frequently found insufficient, those substances should be chosen which can be levigated finely, and which will not have a tendency to wear away the enamel. The testaceous powders, therefore, in combination with some alkaline, should be preferred. Charcoal is highly spoken of. There are, however, two strong objections to it. First, it cuts through hard substances rapidly, consequently will destroy the enamel ; and secondly, it is a very dirty application to the mouth, and others much less so may be readily found. Where, however, it is used, that which is made from the areca nut or from the vine shrub is to be preferred. This, mixed with creta, may be used without injury, where there is a *penchant* for this substance. The best tooth-powders, however, in my opinion, are composed of such ingredients as the following formula :—

“ R Pulv. Cretæ. Prep. ʒiij.
Saponis Hispanici, ʒj.
Pulv. Rad. Iris. Flor. ʒij.
Sodæ Carbon. ʒj. Misce.”

MEDICAL GAZETTE.

“ Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri ; polestas modo veniendi in publicum sit, dicendi periculum non recuso.”—CICERO.

CAN CHOLERA BE EXCLUDED OR CONFINED ?

EVEN before the words we now write have come before our readers, facts may have given a practical answer to our question ; but though we apprehend not so speedy a solution, our deliberate opinion is, that protection by exclusion, though within the range of possibility,

and therefore to be attempted, is no longer within the pale of probable events. The destructive malady has now traversed nearly an eighth part of the earth's surface—it has gone on heedless of man's contrivances—it has baffled every human precaution—it has come even from the banks of the Ganges, and approaches the *divisos orbe Britannos*; and now that it is nearly upon our shores, it scarcely remains for us to say, "Hitherto shalt thou come, and no further!"

We must confess we have long since lost all confidence in the continental system of quarantine and cordons—so far as they might be supposed to protect the nations of Europe against the invader. Russia tried them amply, and to its cost; and if any care was neglected, Prussia guarded cautiously against such neglect. Another powerful nation—Austria, hoping to profit by the experience of both, followed their example in an amended form. Yet what has been the result? Why, Berlin and Vienna—which are even still struggling with the monster—were after all unable to protect themselves from his fatal ingress. Nay, the cordons of Vienna nearly occasioned a civil war; and at Berlin, where they were only maintained by the rigour of strong despotism, the King of Prussia was soon convinced of his mistake, and hastened to repeal those "sanitary laws" which experience taught him were so fruitless, so expensive, so ruinous to commerce, and so tyrannical. In his proclamation (dated from Charlottenburgh, Sept. 6th, 1831) he complains that, "the Asiatic cholera had penetrated into his dominions in spite of measures the most rigorous, precautions the most active, and vigilance the most sustained, which had all proved useless and unsuccessful in averting or even checking its progress." He adds, "and now, since the disease is in our kingdom, and the eyes

of government have been opened by experience, I have ordered the rules, hitherto prevailing, to undergo a complete revision, and a conscientious examination as to all the circumstances worthy of being entertained, in order to arrive at a proper modification of those rules, partly from an acquaintance with the most approved modes of treating the disease, and partly from the exigencies of the occasion. The rigorous measures of isolation by cordons, established on the frontiers, and in the interior of the country, have hitherto acted *unfavourably* on the industrious habits of my people, and threaten, if they be maintained much longer, to destroy the comforts of numerous families, and in short to become *more ruinous to the country than the malady itself*." The Board of Health, at Berlin, was accordingly enjoined to publish forthwith such changes in the "rules" as their experience had suggested to be beneficial; while, meantime, the military cordons were almost everywhere discontinued, and such other restrictions as originated in the (so called) "sanitary laws," were considerably modified.

It is very remarkable, that at the very time the King of Prussia was taking these measures, dictated by his sad experience, and lopping off the heavy expense of cordons, the French minister was procuring a grant of a million from the Chambers to try all the same experiments over again; he was urging even then the salutary effects of *cordons sanitaires*, and insisting that sufficient precaution had not been taken wherever the disease had got admission. He took Prussia for his example. "The Russians, Poles, Hungarians, and Wallachians," said M. d'Argout, "have fallen victims to their own negligence—they have shewn the most culpable contempt for the sanitary measures prescribed by the contagionists; while

the *Prussians*, with persevering and most praiseworthy rigour, have followed up the ordinances of their government—they have spared no sacrifice—they have omitted no precaution—they have resisted the invasion of the disease—and behold their *most signal success!*” Even then, as we have said, the disease was settled in Berlin, and the king was abolishing the cordons. But the knowledge of this fact came too late, and the million was already voted.

To do the French justice, however, all their attention is not now turned to frontier regulations; they seem to be rather intent upon the best method of grappling with the foe when he gets in amongst them: and they have profited considerably by the example of their continental neighbours.

And shall not we, then, weigh well the consequences before we adopt the strict enforcement of similar regulations? Shall we not consider cautiously the certain injury to trade, and the extremely doubtful advantages to the public health? For our own parts *we* have spoken; keep it out, if our fleets on the broad seas can accomplish this; but once among us, we have little faith in any attempt to lock it up, while the whole economy of society must be destroyed in the very attempt.

But if we cannot shut out this fierce intruder, it remains to be considered what we are to do with him when amongst us. Can we hold him in durance? Can we make him our prisoner, and strangle him in his dungeon? Alas! we fear not. He has never yet been subdued in that way. He becomes more bloated and venomous by confinement; he thrives on the thick foul vapours of the lazar-house; he is the monster “that doth make the meat it feeds on.” We should beware, then, how we attempt to isolate the disease. Experience has shewn that it has never yet been shut up, that it has not come forth from its

confinement with increased severity; whilst, on the other hand, it is enfeebled and it languishes in the pure air of heaven. It will not be restrained; it cannot be extinguished; it is in progress; and we will be wise in suffering it, as far as may be, to “pass peaceably.” It will abide with us, we doubt not, in its progress; and it is to the event of that visitation that our attention should be principally turned. We repeat that we can repose no faith in any measures taken for the exclusion of cholera, except the forlorn hope afforded by our quarantine; and we have no confidence in any means of arresting it, if once introduced, except on those which have for their immediate object the abolition of every thing like a *nidus* for its reception. It is in this respect, we think, that the labours of the Board of Health will be most usefully put in requisition. They cannot announce a specific remedy for the disease, because none exists, or at least has been discovered. It has become the fashion to censure this body, for no other reason apparently than that they have not afforded to the public “satisfactory information,” when there was nothing satisfactory to give. Periodicals and journals may, without impropriety, publish every fact or suggestion as it occurs, for the public will estimate these for themselves; and we have been among the foremost to present them with the most interesting details. But the Board of Health are very differently situated; their first care must be, not to mislead. They must sift statements, to separate those which are solid; they must weigh conclusions, to ascertain their real value. To them the public anxiously look, as to an authority by which they are to be guided; and one premature recommendation might be productive of evil which could never be remedied. The public cannot be too strongly cautioned against the nostrums

with which the press is overloaded; they are almost all the products of men writing in their closets, without having seen a solitary specimen of the disease. But, again, it has been said, and with great apparent reason—why are there not among them some who have seen the disease in India? and we confess, that so strong did this objection at first appear to us, that it seemed to be unanswerable. A more extensive acquaintance, however, with the accounts given by the Indian practitioners, and in particular, the circumstance of their opinions having been, in some essential points, refuted by the history of the disease in Europe, have led us to doubt very much whether any advantage would have been derived from the assistance of these gentlemen in the Board. The doctrine that cholera is not contagious, held by the majority of the Indian practitioners, is rendered more than doubtful by its European invasion. The treatment by large doses of calomel and opium, enjoined by most of them, has been tried, and found wanting. The opinions of the Indian practitioners may be of value as regards cholera in India; but the cholera in Europe has refused to conform itself to their views, and we therefore think it would not be prudent to be guided by their opinions. We cannot avoid the conclusion, that a set of intelligent men, with minds free from preconceived notions, and with no favourite theory to maintain, are more likely to arrive at safe conclusions. All the information that is to be had upon the subject the Board of Health possess; and they have availed themselves of the assistance of several intelligent men, who have seen the disease in Asia. They know that a trust of fearful responsibility is reposed in their hands, and that the eyes of the public are anxiously fixed upon them. They number among them some of the most experienced and talented physicians of the metropolis, and they will soon have

the co-operation of the enterprising men now on their return from Russia. While, therefore, we see fully the difficulty of their situation in a period of such alarm, and while we are satisfied that more is expected of them than, in the nature of things, they can effect, we feel assured that a general attention to the directions which—certainly not without due deliberation—they have issued, will do all which foresight can accomplish to mitigate the evil, should all efforts prove insufficient entirely to avert it.

RESUMÉ OF THE POLISH CHOLERA.

At a recent sitting of the French Academy of Medicine, MM. Chamberet and Allibert, members of the Warsaw Medical Commission, assisted; and upon being invited to give the meeting some account of the results of their experience, M. Chamberet rose, and said:—that he had no doubt of the identity of the Polish and Indian cholera: that with regard to *symptomatology*, the most striking circumstances were the epigastric anxiety, the excessive and multiplied discharges from the stomach and bowels, the cramps, the sinking of the features, &c. The disease, he continued, suddenly attacked those who were apparently in the most perfect health. On the second or third day the nervous symptoms prevail: the patient is like one *deadly sea-sick*: he is in a state of idiotism. If, however, he gets over the fourth or fifth day, he will probably recover.

The great predisposing cause, M. Chamberet is of opinion, is a peculiar state of the atmosphere; but besides this, there are poverty, want of food, and frequently indigestion from surfeiting, which act as occasional causes. The Polish soldiers, who get their rations for three or four days at a time, gorge themselves on the first day, and thus expose themselves an easy prey to the disease.

With regard to the *morbid anatomy* of cholera, M. Chamberet states that inflammation of the digestive tube is never absent except when the malady has proved rapidly mortal. The mucous membrane of the stomach and intestines is lined with a pultaceous liquid, of a greyish colour, mixed with mucous and alimentary matters. The liver is soft; and its membrane detachable with the greatest ease. The gall-bladder distended with a large quantity of greenish bile. The venous system is gorged with thick black blood; the urinary bladder generally empty, and contracted, sometimes to the size of a common nut; the meninges are generally injected; and a quantity of limpid, and sometimes bloody serum, is contained by the arachnoid and rachidian membranes.

As to *treatment*, numerous have been the articles of medicine employed, but all of them apparently with equal success. Calomel and nitrate of bismuth have been much lauded. Dr. Leo put twenty-two patients on the nitrate, and twenty of them died. Thirty were put on calomel, twelve of whom recovered, and the remaining eighteen died. But the approved method adopted by the committee was this:—bleeding; warm infusion; spirituous frictions; and sinapisms applied to a large portion of the surface of the body.

And as to the question of *contagion*, the whole body of the Polish physicians reject the doctrine *in toto*. The disease, it is true, broke out at Warsaw on the 10th of April, after a bloody engagement between the Poles and Russians, but weeks and months before this, it has been ascertained that the cholera prevailed sporadically in the country. One physician, in particular, distinctly noted three fatal cases; there is at least, then, some uncertainty about its origin. But it is remarkable, that there were about

a hundred physicians, French, English, and German, employed about the sick in Warsaw, none of whom suffered from the cholera; ten of them even inoculated themselves with the blood of choleric patients. Nor were the porters or nurses of the hospitals, nor the undertakers, less exempt from the disease than the physicians. M. Chamberet added, that he had never seen cases that had been left totally destitute of medical aid; but the physician-general had, and he affirmed that the mortality was not greater among them than among those who enjoyed medical assistance; and that mortality was, probably, on the whole, about fifty per cent.

The thanks of the Académie were voted to M. Chamberet for his very satisfactory communications.

CLINICAL LECTURES,

Delivered in the Dispensary of the London University,

BY

DR. ANTHONY TODD THOMSON.

LECTURE II.

October 22, 1831.

Rheumatism.

GENTLEMEN,—In pursuance of the plan sketched out in my introductory lecture, I have selected four cases from amongst those admitted during the last week, as the subject of this discourse: they are those of James Pennifather, twenty-two years of age, a poulterer; Sarah Parker, a laundress, aged thirty; Elizabeth Sparrow, a laundress, forty four; and James West, a bricklayer, fifty-four. The disease under which these four persons are labouring is marked *rheumatism* in the case-book. They were all, with the exception of Pennifather, who had been for some time ailing, previously in a good state of health; and I am anxious to direct your attention to this fact, as it is one of the features which distinguishes Rheumatism from Gout. In one only of these cases, that of West, did the mode of attack correspond with the usual nosological description of acute rheumatism: this patient was seized with rigor, followed by pain in the knees, shooting along the limbs in both directions, which continued with more or less severity for nearly a week; it then sud-

denly left the limbs, and affected the head, particularly over the forehead, where it has ever since continued. It increases in the afternoon, and attains such a height as to prevent him from sleeping until near the morning, when he perspires profusely. He feels languid during the day; the bowels are lax; the urine is nearly natural; the tongue furred; the pulse 84, and sharp; and the skin clammy. In Pennifather, the rigor was slight preceding the pain, which suddenly attacked the side and the back part of the head and neck, and has been unattended by any remission or intermission. He perspires much at night. The bowels had been freely opened by a Calomel pill and purgative, three days before he presented himself at the dispensary, and they are still open; the urine is high coloured; the tongue clean and moist; the pulse 108, and soft. In the cases of Parker and Sparrow, the pains, which also followed a shivering fit, and were succeeded by heat and perspiration, attacked the pectoral muscles, and the scapula, passing, as it were, through the chest. In Parker, slight pains, extending from the shoulder to the wrist, were felt before the febrile attack commenced, and these gave way when the thorax became affected. The increase of pain at night, the perspirations, and other symptoms, were nearly the same as in the other cases. Sparrow is troubled with a slight cough, which leads me to remark that Rheumatism has been observed to alternate with habitual cough and expectoration, these always recurring after the decline of the rheumatic attack, and being as regularly suspended during its presence. It also, occasionally, alternates with cutaneous eruptions; and I have witnessed more than once its alternation with Hæmorrhoids.

Now, gentlemen, the history of these cases displays the difficulty of framing any general definition of a disease. In one circumstance only, that of the augmentation of the pain by external heat, do they all accord with the definition of Dr. Cullen; and in none of the cases, except West's, were the pains first felt in the large joints. Another exception to the description of authors meets your eye in the appearance of the urine, which is generally said to be high-coloured in the beginning; whereas in these cases it was natural, and only in Parker's did it assume a high colour, on the second day after she presented herself at the Dispensary; and which it has since maintained. This may be accounted for by the sweats in her case being more profuse than in the others. In none of these cases has it yet deposited the pink sediment which is usually perceived in it after the fever assumes an intermitting character, but which is not, however, characteristic of Rheumatism, as it occurs in Ague, Gout, and many other acute inflammatory diseases. The most copious de-

posit of this sediment which I ever witnessed occurred in a case of Hypertrophy of the heart, with Dropsy, which proved fatal. But you will find that in Rheumatism the urine is neither always high-coloured nor deposits pink sediment, and that the pains attack every part of the body. In youth they are said to affect more generally the head, the muscles of the chest, and the upper extremities; and in adult age, the hips, thighs, loins, and back; and this observation is verified by the cases before us. Parker's case, also, apparently confirms the remark made, I forget by whom, that, when the breathing only is affected the pectoralis major is the seat of pain; but that, when both the major and minor are affected, there is, besides, an acute pain, which seems to dart through the thorax, between the breast and the scapula. When first Parker was attacked with pain under the breast, the breathing was impeded; but when it had continued for twenty-four hours, and may be supposed to have extended to the deeper-seated muscle, every inspiration was accompanied with pain, passing from the breast through to the scapula.

In these recorded cases the pain was accompanied by neither swelling nor redness; but in one of those not recorded, that of Sarah Padwell, a young, plump female, the wrists were much swelled, and painful to the touch, although not at all red. When redness occurs in Rheumatism, it differs from that which characterizes Gout, in not presenting the shining appearance, nor being accompanied with the tension always more or less present in gouty inflammation.

The age of the youngest of these patients is twenty-two; but I have met with instances of the disease in children of seven years; and you will find that it is limited to no period of life, from five years to extreme old age, but the greatest number of cases occur between fifteen and thirty. Besides these four patients, three other cases of Rheumatism have been admitted during the week, which is rather at variance with the received opinion that the disease prevails more in the colder than the warmer seasons. I am disposed to ascribe its present prevalence to the sudden transition from dry to rainy weather. In the year 1826 the summer was unusually hot and dry; but after the 18th of August a considerable quantity of rain fell, and numerous cases of Rheumatism appeared, although scarcely any were seen before the rains set in.

Few as these cases are, they enable me to point out to you, gentlemen, the frequency of metastasis in Rheumatism. In West's case the pain suddenly left the limbs, and attacked the head. This individual is of a sallow complexion, and of a comparatively weaker habit of body than the other three patients. Nothing is so much to be dreaded in Rheumatism as a translation of the pain

and inflammation from the joints or muscles to a vital organ—the brain, for instance, or the lungs, kidneys, or stomach. It is sometimes the result of the improper application of rubefacients; and it is also said to follow copious and repeated venesection, but occasionally it occurs without any obvious cause. When it affects the brain, and death *immediately* follows, which I have seen twice happen, no appearances indicative of previous inflammation can be detected either in the membranes or in the substance of the organ; but when the fatal issue is not so instantaneous, the membranes generally display great vascularity, with adhesions, a deposition of gelatinous matter on the pia mater, and also a deposit of fibrine, forming adventitious membranes. There is commonly great dryness of the dura mater, and a smaller quantity than usual of fluid is found in the ventricles. In a case of metastasis to the lungs, followed by Chorea, which came under my notice in private practice some years since, and terminated fatally, the left phrenic nerve was found to be in a highly inflamed state, with considerable congestion of the pulmonary vessels, but no other appearances of diseased action were detected. Fatal metastasis, however, is of rare occurrence; in upwards of a thousand cases which I have seen, four only proved fatal, from the translation of the disease to a vital organ.

In two only of the cases of Rheumatism admitted in the last week, including those under consideration, have I been able to trace the exciting cause of the disease. West ascribes his attack to working two days in a damp cellar; and Elizabeth Sparrow refers her's to having lately removed into a lodging which is damp. Water, indeed, in a state of vapour, seems to be the principal and most frequent remote cause of Rheumatism. A query thence arises, at what temperature does it acquire its noxious influence? From the disease occurring, even in warm climates, in rainy seasons, we might, *a priori*, suppose that a low temperature is not necessary for this purpose; but that there is some fallacy in this inference may be concluded from the results of a series of observations and calculations made by Mr. Gorrie, in the Carse of Gowrie, in Scotland, on the rain gauge and thermometer in 1823-4-5; from which the fact appears to be established, that the greater the fall of rain in a given season, the colder that season will be found to be.—(*Horticult. Trans.* vol. vi.)

I would venture here, gentlemen, to throw out an hypothetical conjecture, which, if it do not enlighten you, may afford an exercise for your minds; knowing that much hydrogen is evolved in fogs, is it not probable that this is also the case whenever the atmos-

phere is surcharged with aqueous vapour? and as Professor Leslie has ascertained that the process of cooling proceeds more rapidly in hydrogen gas than in atmospheric air, how far is this likely to operate as a cause of Rheumatism? It is a well-known fact that the disease is often produced at sea, by frequent washing the decks, a custom now judiciously frequently dispensed with. This observation is also confirmed by the accounts of voyagers in different parts of the globe. In Weddel's voyage towards the South Pole, we are told that when the ships were in latitude $61^{\circ} 44'$, longitude $31^{\circ} 13' 15''$, having had a long course of dense fogs and fresh gales, the decks of the vessels were constantly wet, which produced amongst the seamen colds, agues, and *rheumatism*. As the voyagers in this case were far from land, and yet agues appeared, it may be asked whether the vegetable matter of the decks can affect the decomposition of the water, and produce something analogous to marsh miasma? In the account of Kotzebue's voyage of discovery, we are informed that near the Coral Islands, during frequent rains and gusts of wind, a sailor was attacked with Rheumatism, and another with Sciatica, (vol. 2, p. 338, Trans.) Near Luçon, in the Chinese seas, Rheumatism manifested itself on account of the great dews that fell even before sun-set, (*ibid*, p. 339); and again, "immediately after we left Manilla Bay, (says Kotzebue) the heavy night-dews, in the neighbourhood of the high land, caused catarrhal and *rheumatic fevers*," (*ibid*, p. 342). Rheumatism is very common in Switzerland, in situations confined between chains of high mountains, exposed to damps, and great variations of temperature; and in Canada the lumberers, who fell pines in the woods, and are exposed to great damps and chills, are generally the victims of Rheumatism. There can be no doubt, therefore, that moisture is the principal cause of acute rheumatism; but, it may be asked, does this operate in producing the disease by checking perspiration? To reply to this query, gentlemen, would lead to a long theoretical discussion, rather out of place in a practical discourse; it is of more importance to determine the length of time which elapses between exposure to moisture and the attack of the disease. In West's case it was six hours; and in general I have remarked that it is within twelve hours. Dr. Haygarth, (*Clinical History of Diseases*, Part I.) in noticing this period, which he terms the "latent period," referring to his tables, says, "out of twenty-one cases only four exceeded the period of forty-eight hours. The shortest time noted is half an hour, but I believe that the cause and effect are sometimes connected together without any interval of perfect health."

With respect to the treatment of this dis-

case we can yet say little, as far as relates to the cases before us, as Pennifather only can be considered in a state of convalescence. By looking into the Case-book, you will find that the same means were employed in his case, West's, and Parker's. He and West were cupped upon the nape of the neck, and sixteen ounces of blood abstracted; and the bleeding was immediately followed by the administration of a pill containing five grains of Calomel and two of extract of Opium; a mixture was also prescribed for each, containing four fluid drachms of the wine of the seeds of Colchicum, a fourth part of which was taken every sixth hour. In both, the pains were much relieved on the following day, and in Pennifather they were completely gone on the 18th; at which time also the pulse had fallen to 72, and was soft and regular. He was then ordered three grains of sulphate of Quinia, in ζij . of infusion of Gentian, to be taken three times a-day. On the 20th he continued still improving, and his strength much increased; $\mathfrak{M}vii$. of diluted sulphuric acid were added to each dose of his mixture. To day (22d) he says that he felt strong enough to go to work again; but in the morning he had a renewed attack of the pain in the back of his head, which, in an hour afterwards, moved to the forehead, and then left him. As his bowels had not acted for thirty hours, he was ordered a pill with two grains of Calomel and three of extract of Henbane, and a purging draught for the morning, and, after their operation, to continue his mixture. In Parker, twenty ounces of blood were taken by cupping between the shoulders, and the same medicines prescribed as in Pennifather's case. Here the Colchicum produced nausea and vertigo until it operated. One stool followed each dose. She was much relieved, and continued free from pain until the morning of the 20th, when the pain, but in a less degree returned, and continued the whole of the day. She perspires on the least exertion; the urine is high coloured, but clear; the tongue reddish, and slightly furred. A pill, containing seven grains of Calomel and four of extract of Henbane, was ordered for bed-time, and a strong purging draught for the morning, with the mixture to be continued.

The employment, in acute rheumatism, of Opium and Calomel after bleeding, was, I think, introduced by Dr Robert Hamilton, of Lynn Regis, in 1764, but his dose of Opium seldom exceeded one grain; and he occasionally combined tartar emetic with it. In my own practice, I have long since discontinued the free use of the lancet in Rheumatism, and also the constant use of diaphoretics; and have trusted to a single local or general bleeding, where any was necessary, following it with a large dose of Opium, from

two to three grains, in combination with from six to ten grains of Calomel, and a purge in the morning; which, notwithstanding Sydenham's condemnation of opiates, however acute the pain, has almost in every instance been followed by relief.

In the early part of my practical career, when fresh from the schools, I bled freely in Rheumatism, and repeated the bleedings; but I soon found that the buffy coat and cupped state of the blood continued to shew themselves on each bleeding, until the strength of the patient was reduced to an alarming degree. This was sufficient to set me to think for myself, and I have scarcely used, or ordered to be used, the lancet for upwards of twenty-five years, in acute rheumatism. When the symptoms authorize the abstraction of blood, I find every indication answered by cupping over the seat of the pain; but it is only when the pain attacks the head, or thorax, that I find it requisite.

I have rarely seen much benefit derived from Colchicum until it purges, provided this do not occur too soon after it is taken; in which case, although it purges, yet it does not bring away bilious stools, and little or no rosacic acid; the pink sediment appears in the urine. When this rapid purgative effect occurs, it is necessary to combine the wine of Colchicum with Magnesia, or some alkali, by which the irritability of the stomach and duodenum is allayed; and thence the Colchicum has time to stimulate both the hepatic and pancreatic ducts, and to be taken into the system. If it still run off by the bowels, I order the powder of the bulb, and combine it with the compound powder of Ipecacuanha. Were I to venture to theorize respecting its action, I would refer much of the benefit derived to its operation on the liver, and the influence of this organ over the function of the kidney, causing the excretion of rosacic acid, which appears to be critical in this disease. The reciprocal influence of the liver and kidney on one another, is well illustrated by an experiment of Dumas and Prevost. They cut both kidneys from a dog, and on examining the body after the death of the animal, they found the liver inflamed and the gall-bladder turgid with greenish or deep brown bile. The effect of the Colchicum in augmenting the proportion of the rosacic acid which is passed by the kidneys, is illustrated by observations of Professor Chelin. In a severe case of Gout, he ascertained that, before the use of the wine of Colchicum, the quantity of the acid deposited, both free and combined with Ammonia, was0.069

On the 4th day of using the wine, 0.076

8th day 0.091

12th day 0.112

When the disease assumes its chronic or protracted form, I have seen the solution of tartar emetic more useful than any other

remedial agent. I order gr. vi. of the tartrate of antimony and potassa to be dissolved in \mathfrak{z} vi. of distilled water, and taken in doses of two table-spoonfuls every fourth hour, so that the six grains may be administered in twenty-four hours. The two first doses generally produce vomiting; but the others only slight nausea. The disease commonly yields to this treatment in the course of six or eight days.

I shall reserve any remarks on my observations respecting the use of bark and Quinia in the latter stages of Rheumatism, until we have seen the result of the cases now under treatment*.

REPORTS OF CASES OCCURRING AT PUBLIC INSTITUTIONS.

GENERAL DISPENSARY.

Operation for Stone, with Clinical Remarks.

WILLIAM HENRY LOOKER, aged three years and eleven months, was admitted under the care of Mr. Coulson, October 21st, 1831. The mother says that the child has been afflicted for these last eighteen months with a "complaint in his water," and that latterly the child's sufferings had been most acute, particularly when it passed its urine. He was sounded and a calculus distinctly felt. The boy's health had of late very much suffered, from the constant pain and irritation under which he had been labouring.

Saturday, Oct. 22d.—Mr. Coulson operated on the child. A lithic acid calculus, of the size of an almond, was extracted; and, during the extraction, a small one, of the size of a large grain of wheat, fell on the ground. The operation was completed within the minute.

This is the third dispensary patient on which Mr. C. has operated for stone since April last. The child is doing extremely well.

After the boy was put to bed, Mr. Coulson made the following observations:—Gentlemen, you are aware that a mode of relieving a patient with stone is now coming into use, by which the cutting process is avoided, and the stone is reduced to minute fragments in the bladder, either by crushing or drilling it.

Nothing, I can assure you, would give me greater pleasure than to see the necessity for

performing the lateral operation entirely dispensed with; for though a surgeon may well be proud of performing operations with celerity and safety, there is an object of still higher importance, and more worthy of his ambition, which is the lessening, as far as he can, the necessity for their performance at all. But there are cases in which, I fear, the lateral operation for stone will always be necessary. The child on which I have just operated is an illustration of this.

The clergyman of the parish in which the mother resided, from the most humane motives, recommended her to take the child to Baron Heurteloup. The Baron saw the boy two or three times, and after mature deliberation on the case, sent a note to the mother, of which the following is an extract:—"For such young children his operation is less favourable and safe than for grown-up persons; and the old operation is, in cases of very young children, less dangerous and less to be dreaded. Under these circumstances the Baron would recommend Mrs. L., as the most prudent and safest plan which she can follow, to have the stone taken out by the cutting operation, and that without delay." Such are the observations of the Baron Heurteloup, and I am sure that you cannot fail to be struck with the frankness and candour with which this ingenious man delivered his opinion on the merit of his own mode of operating. The ardour of enthusiasm has not blinded his judgment, but he candidly acknowledges some of the cases to which his operation is least, or not at all, applicable. Prior to performing the operation for stone, the surgeon should be extremely particular in preparing his patient, by those means which experience has shewn to be best conducive to this end. Celsus was aware of the necessity of bringing the patient into a fit state for the operation, by diet and abstinence; in fact, the most successful lithotomists are those who are most attentive to this point. Mr. S. Cooper, in his *Surgical Dictionary*, or at least in the edition which I have, has given no practical directions on this most important point. Obsolete instruments, and obsolete modes of operating, are detailed with minuteness, and this indispensable part of the treatment of a lithotomy patient is not at all alluded to. If the patient's health is much impaired, and the bowels are relaxed, which is not unfrequently the case in children, you must, before the operation, lessen the irritability of the bladder and bowels by an anodyne, and improve, as far as you can, the patient's health, by medicine and attention to diet. I generally give, on the night preceding the operation, a few grains of hydrarg. c. creta, with the pulv. rhei, and early on the following morning some castor oil. Two clysters should be given before the operation, one two or three

* In Dr. Thomson's Lecture inserted last week, for "*res angustie domi*," read "*res angustie domi*."

hours after the oil, composed of gruel, olive oil, and salt; and the other about an hour before the operation, with common gruel and twenty or thirty drops of laudanum in it. If, when the surgeon arrives to perform the operation, the last injection has not come away, he should urge the patient, if he be an adult, to go to stool; if, however, it is a child, it will generally happen that, if the injection has not passed off, it will do so at the time the staff is introduced. On no account should the surgeon undertake the operation till the injection has come away. The patient should be placed on a table of sufficient height, so that the perineum be opposite to the breast of the surgeon. The table should rather be a little too high than too low, for it will be an advantage to you in the operation to be a little under your work than above it. After the patient is bound, his shoulders and back should be raised and supported with pillows; he should be brought to the edge of the table, and his thighs be widely separated by an assistant; but it is of great importance that the nates be kept straight, and that an inclination be not given to one side more than the other. I now introduce a curved staff, and give it to the care of an assistant. You no doubt observed that Mr. Pereira, who held the staff for me (and has done so on two or three other occasions), gave to the instrument a different direction to that in which it is usually held. Instead of holding it perpendicularly, or nearly so, Mr. P. inclined the handle a little towards the ground, with the groove turned towards the left side. By this inclination of the handle, you certainly make the groove of the staff less prominent in the perineum; but there is this advantage, when you have cut into the groove, you have no occasion to alter the position of the staff, and the fore-finger of your left hand is quite at your disposal for protecting the rectum, and guiding the knife. I find that I can perform the operation much more rapidly in this way, than by taking the staff into my own hand. M. Langenbeck is a strong advocate for this mode of holding the staff; he, however, advises the handle to be inclined still more towards the ground than I do. I begin the first incision rather low, about two fingers breadth above the anus; the bulb of the urethra will be then avoided. In fact the external incision, if commenced higher up, can be of no use to you; and I find that this, the upper part of the wound, is often the slowest to heal. Respecting the remaining steps of the operation, I have little new to offer. For the division of the prostate I use the long straight knife, with the beak in the middle line of the point. I began in 1828 with the gorget; but whatever merits this instrument may possess in the hands of an experienced operator, I feel confident that, for a beginner at

least, the knife is the safest and best instrument which he can employ. If any hemorrhage occur, you must endeavour to compress the bleeding vessel with your finger.

The after treatment consists, if no inflammatory symptoms ensue, in merely keeping the patient quiet, though it is extremely difficult to carry this into execution with children. The knees by some surgeons are tied together; by others they are not; but they should always be kept raised, and the scrotum supported. No application is required to the wound; but the urine should be received on sponges, and the parts kept clean. Some urine soon begins to flow through the natural passage. In a man above sixty, on whom I operated some time ago, a considerable quantity of water came through the urethra on the morning following the operation. The time, however, varies at which the water entirely ceases to pass through the wound; and in some rare cases urinary fistulæ remain.

PRACTICAL DIRECTIONS REGARDING CHOLERA.

[The following memorandum on the subject of cholera has been issued by the Board of Health. The "rules and regulations" intended to prevent its introduction, and which recently appeared in the London Gazette, we shall probably take another opportunity of bringing before our readers.]

BOARD OF HEALTH.

College of Physicians, Oct. 20.

The following are the early symptoms of the disease in its most marked form, as it occurred to the observations of Dr. Russel and Dr. Barry, at St. Petersburg, corroborated by the accounts from other places, where the disease has prevailed:—

Giddiness, sick stomach, nervous agitation, intermittent, slow, or small pulse, cramps, beginning at the tops of the fingers and toes, and rapidly approaching the trunk, give the first warning.

Vomiting, or purging, or both these evacuations, of a liquid like rice-water, or whey, or barley-water, come on; the features become sharp and contracted, the eye sinks, the look is expressive of terror and wildness; the lips, face, neck, hands, and feet, and soon after the thighs, arms, and whole surface, assume a leaden, blue, purple, black, or deep brown tint, according to the complexion of the individual, varying in shade with the intensity of the attack. The fingers and toes are reduced in size, the skin and soft parts covering them are wrinkled, shrivelled, and folded; the nails put on a bluish pearly white; the larger superficial veins are mark-

ed by flat lines of a deeper black; the pulse becomes either small as a thread, and scarcely vibrating, or else totally extinct.

The skin is deadly cold and often damp; the tongue always moist, often white and loaded, but flabby and chilled like a piece of dead flesh. The voice is nearly gone; the respiration quick, irregular, and imperfectly performed. The patient speaks in a whisper. He struggles for breath, and often lays his hand on his heart to point out the seat of his distress. Sometimes there are rigid spasms of the legs, thighs, and loins. The secretion of urine is totally suspended; vomitings and purgings, which are far from being the most important or dangerous symptoms, and which, in a very great number of cases of the disease, have not been profuse, or have been arrested by medicine early in the attack, succeed.

It is evident that the most urgent and peculiar symptom of this disease is the sudden depression of the vital powers; proved by the diminished action of the heart, the coldness of the surface and extremities, and the stagnant state of the whole circulation. It is important to advert to this fact, as pointing out the instant measures which may safely and beneficially be employed where medical aid cannot immediately be procured. All means tending to restore the circulation and maintain the warmth of the body should be had recourse to without delay. The patients should always immediately be put to bed, wrapt up in hot blankets, and warmth should be sustained by other external applications, such as repeated frictions with flannels and camphorated spirits; poultices of mustard and linseed (equal parts) to the stomach, particularly where pain and vomiting exist; similar poultices to the feet and legs, to restore their warmth. The returning heat of the body may be promoted by bags containing hot salt, or bran, applied to different parts of it. For the same purpose of restoring and sustaining the circulation, white wine-whey, with spice, hot brandy and water, or sal volatile, in the dose of a tea-spoonful, in hot water, frequently repeated, or from five to twenty drops of some of the essential oils, as peppermint, cloves, or cajeput, in a wine-glass of water, may be administered; with the same view, where the stomach will bear it, warm broth, with spice, may be employed. In very severe cases, or where medical aid is difficult to be obtained, from twenty to forty drops of laudanum may be given, in any of the warm drinks previously recommended.

These simple means are proposed as resources in the incipient stage of the disease, where medical aid has not yet been obtained.

In reference to the further means to be adopted in the treatment of this disease, it is necessary to state that no specific remedy

has yet been ascertained; nor has any plan of cure been sufficiently commended by success to warrant its express recommendation from authority. The Board have already published a detailed statement of the methods of treatment adopted in India, and of the different opinions entertained as to the use of bleeding, emetics, calomel, opium, &c. There is reason to believe that more information on this subject may be obtained from those parts of the continent where the disease is now prevailing; but even should it be otherwise, the greatest confidence may be reposed in the intelligence and zeal which the medical practitioners of this country will employ in establishing an appropriate method of cure.

HENRY HALFORD,

President of the Board.

CAJEPUT OIL.

M. LAMARE, an old practitioner in the Isle of France, has lately written a strong letter to the Paris Académie de Médecine inveighing against the use of cajeput oil. It is not at all employed by the Indians, he says, in the cure of cholera: it is an *incendiary* medicine that cannot be too carefully guarded against: it may, indeed, be used with some advantage externally in chronic rheumatism; but it contains copper, and is dangerous, &c. In short, he is indignant at the pains which seem to have been taken in the French journals to cry it up, which he attributes altogether to cupidity and ignorance.

The reading of the letter elicited some facts from members of the Académie, who entered into a discussion upon it. The great specific gravity of cajeput oil is, according to M. Laubert, a characteristic of its genuineness, which fraud cannot imitate. Its green colour does not always prove that it contains an oxide of copper, according to M. Caventon: it is frequently produced by an organic colouring substance inherent in the leaves; and the quantity of copper found in it is no more than 1-22nd part of a grain in each *gros*. Neither is the oil caustic, according to M. Pelletier, except when taken quite pure, like the essential oil of peppermint, &c. M. Lamare's letter, however, was thought worthy of being communicated to the journals.—*Gazette Médicale*.

LECTURES

ON

THE THEORY AND PRACTICE OF
MEDICINE ;

Delivered at the London University,

By DR. ELLIOTSON.

LECTURE V.

Explanation of the term Diathesis—Symptoms of Disease—Mode of examining these—Appearances of the Face—of the Tongue—of the Eyes—Risus Sardonicus—Facies Hippocratica—Expression of the Countenance—Examination of the Hand—the Pulse—its Characters.

THERE is a term, gentlemen, which, on reflection, I think I omitted to explain, or even to mention at all—namely, the word *diathesis*.

When the body is particularly predisposed to any kind of affection, it is said by some to have that particular *diathesis*, or a disposition to it. However, you will generally see this term limited to imply two states—an inflammatory state, and a state of weakness, of debility, if not of putrescency. You will hear the one called the *phlogistic*, or *sthenic*, which you know means strong, and the other called the *asthenic*, or weak. When a person, for instance, is in a high state of excitement, with a full and strong pulse and heat of body, and under any particular complaint, he is said to have the *sthenic* or *phlogistic* diathesis—in fact, an active inflammatory state of the body. If, however, the state be one of debility, so that any disease which is actually present is attended with weakness, and still more if by extreme collapse and a disposition to putrescence in its progress, then it is called the *asthenic* diathesis. I believe, in modern times, these terms are rarely used, except

when a certain disease is present, so that they really imply, not the disposition to disease, but the character of the disease—and, indeed, as to whether it is actively inflammatory, attended by strength, or whether it is attended by weakness; but even of these two, you seldom hear persons speak of either, in this country, excepting the *phlogistic*.

I may mention that the word *diathesis* is used by old authors in other senses—to signify the general disposition to disease at any particular season, so that the constitution of the period was said to be its *diathesis*. If the disposition of any particular season of the year—not the regular seasons—were to produce such and such kinds of disease, the word *diathesis* was applied to that disposition—to the disposition, if I may so speak, of the atmosphere at the time. But, generally speaking, the word is used as I have pointed out above.

However, you will find a constitutional disposition to certain diseases, when present, called a *diathesis*. For instance, it is not uncommon, in practice, to hear persons talk of a *scrofulous* diathesis. Where a person has every look of *scrofula*, with its actual presence in one part, you will hear individuals say, that is a *scrofulous* diathesis. A disposition to many other kinds of disease, when present, is sometimes called a *diathesis*, but it is the *phlogistic* diathesis of which we hear the most.

This term is sometimes used to signify that full state of the body which would render a person very liable to an active inflammatory affection; but is certainly more frequently limited to that state when the disease actually has begun. When a violent disease begins, and there is quickness and strength of pulse, and heat, the person is said to have the *phlogistic* diathesis. Now and then, persons with merely a full pulse are said to be labouring under the *phlogistic* diathesis; but that state is characterized more particularly by the word *plethora*, of which I spoke in the last lecture. I stated, that when the blood was

in excess to the strength and to the vessels, true plethora was said to exist—*plethora vera*.

Speaking of plethora, you will pardon me for recapitulating what I mentioned in the last lecture—viz. that there is true plethora, *plethora vera* or *absoluta*—that is to say, out of proportion to the strength or the vessels—*plethora ad vires*, or *plethora ad vasa*. I also stated that a fanciful kind of plethora was mentioned in old authors, where the blood is not supposed to be excessive in quantity, but to be expanded; and that is called *plethora ad molem*, or *plethora apparens*;—and another species of plethora was supposed to exist when the containing vessels were diminished in capacity, so that, though the quantity of blood was the same, the vessels became too small for it; and that has been called *plethora ad spatium*—the space being too small.

In the last lecture I began the consideration of symptoms in general. I may mention that, in some writers, you find symptoms and signs distinguished from each other, but I think it mere trifling to dwell upon such matters. With respect to symptoms, I was going to consider them as they were observable by the patient, or observable by others, because many are observable by the patient alone, and are not cognizable to others; those, however, which others observe, of course the patient, for the most part, may observe likewise. I have considered the chief of those of which a patient alone can take cognizance, and I will now proceed to consider those which the by standers, and particularly medical by-standers, observe.

Now, in observing the symptoms of disease, it is right to remember that providence has blessed us with five senses; and all these five senses it would be ungrateful, as well as unscientific, in us not to employ. I am led to speak in this way on account of its being a modern practice to employ the ear extensively. Those who do so are laughed at as innovators—as people who take unnecessary pains, and are perhaps attempting a piece of quackery, in order to produce an impression upon patients: at any rate they are laughed at: but it will be impossible for them to be laughed at long. If nature have blessed us with hearing to observe certain phenomena around us, there can be no reason for not employing it when we come to observe the phenomena of disease; and if it be a fact that symptoms take place of the most useful nature that are cognizable by the ear only, it is our duty to employ our ears for the purpose of detecting them. We are bound, I think, to employ all our five senses in the investigation of disease. The chief, however, of which we make use, are the sense of sight, the sense of hearing, and the sense of touch; but the smell, and in some instances even the taste, may be called in to our aid; the smell, however, much more frequently than the taste. It would be as ab-

surd to shut our ears as to shut our eyes, yet, because the extensive employment of hearing has only been introduced lately, those who were not instructed in this point when they were students, are, some of them, too proud to condescend to learn in their old age, and are good enough to pity us younger men.

As to those symptoms which are cognizable by our various senses, they discover themselves and are apparent in every part of the body, from the head to the foot; but the two parts which give the chief symptoms to the sight, and I may say to the touch, and the chief symptoms not only in reference to themselves but to all other parts of the body, are the *head* and the *hand*. It has become the custom, in all civilized nations, to cover all parts of the body except the face and hands; and these two parts afford far more information respecting the state of the body, and respecting diseases that are present, and not seated in these individual parts, but at a distance, than any others. It is certainly a striking coincidence; but we must remember that while necessity compels mankind to keep the face, and almost always the hand, uncovered, Providence has ordained that these same two parts shall convey the chief information to others respecting our mind and body at all times.

With respect to the face, we observe that it gives us two sorts of information—first, as a mere portion of the body only, a portion of the surface which is far more affected by every change than almost any other excepting the hand, and therefore so far as it is *face*; and, secondly, it gives us another description of information so far as it is *countenance*, so far as it expresses the state of the mind and the state of feeling altogether. The observations which you make upon this part of the body may be considered as they respect simply *face*, and as they respect simply *countenance*.

With regard to the face as really a part of the surface of the body, if there be fullness of blood it is shewn particularly there. If you were to take the same quantity of surface in any other part of the body—the abdomen, back, or thighs—you would not get the same information from the part, simply as surface, as you do from the face. If the body be at all full, you see it in the face. If the circulation be rapid and the heat considerable, it is the face that shews it; the cheeks become tinged much sooner than any other part. If there be the least degree of coldness, you perceive it in the cheeks, nose, and lips. You discover hectic fever in an instant by the red patch upon the cheek. If the patient be labouring under difficulty of breathing, you find the eyes immediately suffused, you find the lips more or less livid, and the whole face frequently of a leaden hue; sometimes, indeed, I have seen it black. If it be jaundice that the patient

labours under, you discover it instantly in the face; by one part of the face you will detect it long before it appears in any other part of the body except the hand; and when the disease has nearly declined, it is in the face as well as the hand that it lingers the longest. In the white of the eye you perceive the presence of jaundice before it is apparent any where else, except at the root of the nails. If the patient be bloodless, you first discover it in the paleness of the face, the want of the usual vermilion of the lips, and in the absolute paleness of the tongue; there is not a white crust upon the tongue, but that organ is absolutely blanched. One of the chief marks of scrofula is shewn in the face; there is the dilated pupil and the tumid under lip.

Then, again, in the *tongue* you have an immense number of symptoms. The body cannot labour under inflammation in any part but the tongue becomes affected by it. If there be strength, generally the tongue becomes white; if there be inflammation within the stomach and intestines, it frequently becomes red—red at the tip, red at the sides, perhaps red all over, and perhaps there are red stripes upon it. If the stomach be simply in a state of dyspepsia, and the bowels confined, you have the tongue covered with a yellow thick mucus. The indications of the tongue are innumerable; they have been observed from the remotest ages; and no one would think of finishing his attention to a patient without looking at that organ. The tongue sometimes will become brown, sometimes it will become absolutely black. In what are called putrid diseases, where there is a high degree of debility, and a disposition to putrescence, the tongue will become black. In other cases it will become glazed throughout, shining, and glassy; and in this state it will frequently be cracked into the bargain. In other diseases, again, as, for instance, in delirium tremens, it is frequently covered by a creamy mucus—not a thick yellow mucus—it is moist, not dry—but a mucus more like cream than any thing else, and so liquid that the tongue is moist. I need not insist upon the great importance of that part of the face or head—the tongue.

Then, again, if we take the *eyes*. We discover in a moment whether there is great excitement of the brain going on by the sparkling of the eyes, by their redness, and by their being watery. We can discover whether a person has headache by the oppression shewn in the eyes; and in some affections of the head, the eyes squint—are contorted in various ways. Frequently, too, when a person is asleep, he does not completely close his eye, and that is often an indication of disease. Then, again, the state of the pupil is very characteristic of many affections of the head. If you take

the eye altogether, there is generally an appearance of brilliancy, or of dulness; or if you take particular parts, there is a dilatation of the pupil, or on the other hand, an extreme contraction; and all these things it is of the highest importance to observe, because they point out particular affections. For example, if you take apoplexy, you see the pupil usually dilated, and you know that there is great oppression of the brain; but if the pupil be amazingly contracted—reduced to a pin's point, you may almost to a certainty say that the patient will die: I do not say it is *absolutely* certain, because it is wrong to speak positively. If a person have taken opium in a large quantity, there is the same effect produced—generally a great contraction of the pupil; and where you are not with certainty informed of the patient having taken this narcotic, the appearance I have just described will assist you materially in forming the diagnosis. Then besides the strabismus, and the open state of the eye during sleep, you have contortions in various instances, particularly if a child have convulsions of another part of the face—convulsions of the muscles of the lower jaw, so that he gnashes and grinds his teeth together during sleep, and his eyes roll.

From the state of the *orbit*, or at least the contents of the orbit around the eye, you judge of the extreme debility, exhaustion, and emaciation of the patient. If the parts around the eye become absorbed, the eye sinks back in the orbit, and a hollowness is produced, which is characteristic of extreme exhaustion and inanition, and this alone will enable you to say in a moment how much worse the patient has become.

From the *face altogether*, simply as a part of the body, you are able frequently to tell at once that the lungs are affected, or that there is a great disposition to affection of the lungs. It is impossible sometimes to doubt for a moment that if the patient be not labouring under phthisis, he soon will. From the peculiar appearance of the countenance altogether, particularly from the appearance of the eye, its transparency, together with the languor of the cheeks, or the flush upon them, no doubt can exist as to the nature of the disposition. And with respect to other parts, you can tell that the patient is labouring under organic disease of the abdomen from the look of the cheeks: I do not say it is so always, but the appearance of the face is of great use in enabling us to detect that circumstance. In organic diseases of the stomach, intestines, and surrounding parts, you have often a faint greenish yellow appearance of the face, something like that of a faded leaf, with minute vessels, not forming a patch of red, as in hectic fever, but reticulated, like net-work, on the cheeks. Where

you observe this, there is generally some part of the abdomen in a state of organic disease. You discover the strength of a patient in a moment by his countenance. When you are attending a case of fever, there is frequently no occasion to ask a question: you can tell whether a patient is better or worse by viewing his countenance. So with respect to many other diseases, when the patient is getting either better or worse, you can tell immediately by his face, what change has taken place subsequently to your previous visit. Every body makes this observation; and hence, when an individual meets a friend, he tells him that he looks well, or he is sorry to see him ill. If the appearance of the face be so characteristic of the state of an individual's health to an inexperienced person, how much more so must it be to the medical man who studies minutely every shade of change and difference that takes place in each particular part!

Speaking of convulsions of the face—such as squinting or contortions of the eye, or a grinding and gnashing of the teeth, I may state that there is one set of convulsions about the mouth which is mentioned under the term *risus sardonius*: it is a horrid sort of grin which you often see in persons who are about to expire. To me it is the most terrible of all sights. It has been thought to characterize inflammation of the diaphragm, but I do not know whether that is the case—inflammation of the diaphragm is a rare affection. It is common, however, for persons at death's door to grin frightfully. The phenomenon receives its name from a herb which grows in Sardinia, of a poisonous quality, and said to produce in those who eat it this horrid contortion of the mouth just before death.

You likewise see a singular appearance of the countenance, mentioned by almost every writer under the title of *facies hippocratica*; it is the usual appearance of the face immediately before death, when the body is at last completely exhausted, and life about to be resigned. It is so called because Hippocrates gave a most accurate description of it. His description is, sharpness of the nose, hollow-ness of the eyes, collapsed state of the temples, collapsed and contracted state of the ears; the edges of the nostrils everted; the skin of the forehead firm, tense, and dry; paleness of the whole face, perhaps even blackness, or a livid and a leaden appearance. These are the characteristics of the *facies hippocratica*. When you see a person dying from a disease that has exhausted him gradually, this is exactly the appearance of the face.

I may mention, although it is not in regular order, that among the symptoms of phthisis, one is taken from the teeth; not that all phthisical patients have the same state of

the teeth, but in many there is a beautiful whiteness of the teeth, with a degree of transparency and brilliancy which is comparatively seldom seen in persons who are not disposed to phthisis.

Speaking of eruptions, I may mention that the exanthematic and acute inflammatory cutaneous diseases, shew themselves much better on the face, for the most part, than anywhere else. It is on the face first that you discover a child is going to have the measles. When a child is in a state of pyrexia, and you are sure it is going to be ill of something or other, the face will first disclose it, if it be the measles. There you have the running of the eyes—there you have the fulness; and the first papule that present themselves are generally seen on the face. Most acute cutaneous diseases attack the face among the earliest parts; or, if they do not, yet the face, if affected, discovers the true nature of the disease better frequently than any other part; the reason of which is, that the face is much more vascular than other parts. The cheeks are more or less inclined to be red in most individuals, and the least feverishness reddens the face more than any other part of the body; and therefore it is that acute cutaneous diseases generally shew themselves best in that situation.

With respect to the face simply as a part of the surface of the body, you discover paralysis in it more easily than in any other part. If a person be sitting still, you cannot tell whether his arm or his leg is paralyzed; but if his face be paralyzed, you will generally in an instant discover it by the part affected being drawn to the opposite side, and perhaps from his inability to swallow his saliva. And so with regard to the tongue; the moment the person begins to speak, you frequently in paralysis can discover the existence of the disease; the tongue frequently in paralysis moves to one side, but it generally moves in an opposite direction to that in which the mouth is drawn. In fever, and other diseases, the tremor of the tongue is very characteristic. In general the whole body trembles, but the tongue does so particularly. In paralysis agitans, if the person lie still in bed, yet if he put out his tongue, it is seen to be in a great degree of tremor. In cases of dyspnoea and apoplexy the tongue is swollen.

But the face is particularly indicative of the general state of the individual's mind, and of the general state of the strength likewise; and we then, perhaps, should rather call it the *countenance*, and speak of the countenance than of the face—the countenance being the term generally used in reference to the state of the feelings. You will judge directly whether a patient is in pain or not, whether he is suffering, by the countenance. In colic, and in enteritis, the

agony is so depicted in the countenance that you in an instant discover that something must be wrong. I need not say that in insanity that passion of the mind which is predominant discovers itself in the countenance. You may at once detect a good-natured, a furious, a proud, or a desponding maniac. You may also discover much by the way in which his head is carried, to say nothing of his countenance. Those that are proud, carry the head upright; those that are cast down, carry it the reverse. But the countenance, independent of the position of the head, is indicative of the character of the disease; and again, an idiot is almost immediately discovered by the expression of his face. You ascertain in a moment by the countenance what the person's feelings are with respect to strength as well as to comfort, and what passions of the mind are predominant. You discover, as I before-mentioned, whether a person is better by observing his face, by noticing whether it looks fuller; but you discover much from the very expression of the countenance. You see, therefore, what a vast source of information is given by the face, not with respect to affections of that particular part, but with respect to all other parts of the body.

Speaking, however, of the general expression of the face, I must mention that you learn a great deal of the patient's feelings by the attitude of his body. In fever nothing is a more unfavourable omen than for a patient to be seen lying on his side at first, and gradually getting on his back till he lies altogether on his back; but when he sinks also in his bed, the case becomes still more alarming. The reason is simply this—more muscular strength is required in order to lie on the side than on the back, and to remain in a firm posture than to sink down; and therefore, when a patient sinks down, it is an indication that his strength is nearly exhausted. You discover a great deal, too, by the restlessness of the whole body. One of the most unfavourable symptoms in many diseases is extreme restlessness. You may have restlessness in women from mere fidgets; but in acute diseases, when great debility has come on, restlessness is often one of the fatal symptoms.

Of course, if disease take place in the face locally, it will shew itself there as in other parts of the frame, whether it be swelling, mortification, local cutaneous disease, or whatever else happens to it.

But again, to go to the *hand*, the part which, together with the face, in all civilized and uncivilized countries is most exposed. In the hand we have also very great indications, though certainly they are not so strong as in the face. The hand is one of the extreme parts, and shews the first fall of temperature. It is one of the first parts that be-

come cold, exactly as the nose and ears do in the head. I believe the difference between its temperature in fever and in health is often greater than the difference of the temperature of most other parts of the body. A cold sweat is shewn in the hand amongst the earliest parts, and the very hectic fever which flushes the face flushes also the palm of the hand, and indeed the sole of the foot; but it is shewn particularly in the palm of the hand, from the greater fineness of the integuments. Difficulty of breathing again, discovers itself by the appearance of the nails. If you observe in the difficulty of breathing a purple hue of the lips, a fullness and a leaden colour of the face, and a purplish colour of the eyes, you discover likewise a purple hue of the nails, at least the parts under the nails. As I mentioned, in jaundice, that the disease appears first at the roots of the nails, as well as in the sclerótica, and after the disease has disappeared from the rest of the surface, you will discover it still lingering in the system by the yellowness observed in the same two parts, so I believe the changes go on, *pari passu*, in dyspnœa with respect to the eyes and nails. The dryness of the hand, its mordent heat, its clamminess, its firmness and softness, the very grasp of the patient, are all significant. If phthisis is often seen in the eye, the ends of the fingers are no less indicative of it or other internal scrofula.

Besides all this, it is in the hand that we easily make the most important conceivable observations upon the state of the circulation. It is in the hand, or at least at the wrist, that we feel the pulse much more easily than at any other part of the body. The same observation might be made any where else; but it would be done far less accurately, and with far less ease, than at the wrist. With respect to all other observations, about temperature, about heat, about cold, about clamminess, and about sweats, I think they are not only all made much more accurately in the hand than any other part, but the hand appears to be affected by these particular symptoms more altogether than most other parts of the surface of the body.

In regard, however, to the *pulse*, great indications of disease are taken from it. You will find the pulse generally spoken of in the first place, as great or small—*pulsus magnus*, *pulsus parvus*; you find it mentioned likewise as strong or weak—*pulsus validus*, *pulsus debilis*; and as hard or soft—*durus*, *mollis*. A pulse may be large, may be considerable, and yet not hard; a pulse also may be hard, and yet by no means large,—on the contrary, it may be exceedingly small. A pulse is not necessarily strong because it is large; neither is it necessarily weak because it is small in volume. If a pulse be both hard and large, it is a strong pulse also; if a pulse be small and soft together, then it must be considered

as weak; and mere softness may be such as to amount to weakness; and if it be exceedingly weak, you may extinguish it by the least pressure of the finger. This pulse has been called *pulsus vermicularis*, and among us *fluttering*, if also quick. It is a pulse easily recognized in practice, and indicates death to be at hand in many cases. If a pulse be exceedingly hard, and at the same time small, then it has been called a *wiry* pulse. A wire is necessarily fine and hard, and a pulse which has the same attribute is called a *wiry* pulse. This is different from a *thready* pulse, because thread is different from wire. A *thready* pulse is merely that which is small, soft, and weak—a *vermicular* motion—hardly worthy of the name of a pulsation. It is chiefly in violent inflammations of the abdomen that you have the *wiry* pulse; however, you must not depend upon the pulse only in such cases. If there be other symptoms of inflammation of the stomach, or the intestines, or the peritoneum, you must not say that is not the disease because the pulse is not *wiry*. These are the qualities of the pulse with respect to its volume, solidity, and force,—large or small, hard or soft, strong or weak.

But there are other varieties of pulse, taken from its *rate*. A pulse may be quick, and a pulse may be slow; there is the *pulsus frequens*, and the *pulsus rarus*. The pulse will sometimes go up to 160; sometimes it will go beyond that, so that you cannot count it, especially if weak; but then you can ascertain the state of the circulation by the heart, where you can count 200 and upwards with perfect ease, when you cannot count the pulse at the wrist. You find a distinction made with regard to a frequent pulse—you find a *pulsus frequens* and a *pulsus celer*; *frequens* is where there is a large number of strokes in a given time, and *celer* is where the strokes take place in a short and abrupt manner. *Pulsus frequens* and *pulsus rarus* are opposite to each other; the former being a rapid, and the latter a slow pulse. The opposite of the *pulsus celer* is the *pulsus tardus*, in which, whatever number of beats take place, they occur in a gradual manner. In England practitioners call this pulse a *jerk*ing pulse: *jerk*ing and *sharp* are our terms corresponding to *celer* in regard to the pulse. No matter whether it is quick or not, we say it is a *sharp* or *jerk*ing pulse; whereas, on the other hand, that which takes place as it were deliberately is called *pulsus tardus*.

I may mention the great importance of feeling the pulse at both wrists. If you feel the pulse at the left wrist only, you may often think that the patient, from extreme debility, cannot bear bleeding; but if you feel it at the right also, you will frequently form a very different opinion. Nothing is more common than for the pulse at the two wrists to vary exceedingly; and it is the pulse at

the right wrist that, in the greater number of cases, is the correct guide. The difference is so great in so large a number of cases, that it should be a general rule to observe both pulses. I never myself have seen the pulses different in point of time, but there is a great difference in respect to force. It is also certainly right, in cases of great nicety, where you are in doubt as to the means you are to use, to examine likewise at the heart; and in cases of local disease of that organ, it is also right to examine the heart itself; for in some diseases you will have simply, from an affection of the heart, a very violent pulse, such as would lead you to bleed to a great extent; and in those cases, the pulse is not an indication of the general strength of the patient, but receives its character solely from the disease of the heart. On the other hand you will, in some diseases of the heart itself, find a very small pulse, and on examining the heart you hear it beat violently, but through a diminution in the aperture the blood escapes in small quantity. It is right to examine not only both wrists where there is great nicety required, but I also advise you to listen to the heart.

I should likewise mention with respect to the pulse, that its rate, size, and force, are sometimes irregular; it will vary in its strength and size at different beats, and it will also vary in its frequency. You will sometimes have a pulse merely irregular, beating always with nearly the same force, but beating at an irregular rate, and that is an irregular pulse in the common acceptation of the word; but besides that, you frequently find it irregular in force, size, and frequency, so that it will give a great thump or two, and then you have a number of strokes of no strength at all, and then again it will beat violently. Irregularity, therefore, you must remember, does not refer to frequency only, but likewise to force. Sometimes the pulse intermits.

You must also of course remember, as physiologists, that the pulse differs in every age; that the younger we are, the more quick is the pulse; that the pulse of the female is quicker than that of the male; and that, generally, the inhabitants of a warm climate have a weaker pulse than those in a more temperate latitude. It is necessary to take all these things into consideration, because, if you were to find the pulse of a child 120, and that of an adult labouring under fever likewise 120, you would commit a great error in supposing that the child likewise laboured under fever. It is necessary, therefore, to remember that the pulse varies according to age, sex, and climate, and that in young children it is particularly quick. I had an instance last week of the great use of examining a patient in bed, and not being contented without what is contemptuously called a *mechanical* exami-

nation, in an enlargement of the abdomen. I was called to visit a lady in the family way, about thirty years of age, whose pulse was about 80 or 90, but on listening to the abdomen—she being single, and having some disease, as she said—on listening to the abdomen, there was another pulsation about 123. The pulsation did not arise from any of the branches of the iliac arteries; that was impossible; for if they had beaten, it would have been at the same rate as the pulsation at the wrists. She had a pulse of 80; something within her had a pulse of 123; and what that was, I left her to settle by herself. Being a single lady, all that I could say was, that if she waited patiently, the whole of the disease would come away to a certainty in two or three months.

ON THE USE

OF

PURGATIVE MEDICINES IN INFLAMMATORY AFFECTIONS OF THE STOMACH AND BOWELS.

To the Editor of the London Medical Gazette.

SIR,

THERE is scarcely any probability that medicine will ever become quite free from the imputation of being a "conjectural art." The human frame is liable to be affected by so many agents, both physical and moral; the functions of its several organs are performed in a manner so complicated and mysterious, that, when any morbid change takes place in it, it is often extremely difficult, if not impossible, to discover either the cause or the nature of that change. But, in addition to this grand obstacle in the way of medical science, there are other subordinate ones, with which it is of more importance to be acquainted than with even the primary one itself. For this last, originating in the nature of the subjects which the science embraces, is inseparable from it; while the others, being purely accidental, admit of being removed.

Among the most powerful of these accidental impediments may be reckoned the readiness with which the generality of those who cultivate medicine submit to be influenced by the example and the authority of their predecessors. For thus their thoughts, starting from the same point, and running in exactly

the same line, reach, of necessity, the same conclusion; and by this repeated iteration the track is, in process of time, worn into so deep a groove that none but an intellect of extraordinary powers can effect a deviation from it. The consequence of this is, that when once an error is adopted by a few persons of reputation, or even by a single person of marked celebrity, the great body of the profession is drawn after, and a long time must elapse before that error can be got rid of. For it is not often that we meet in any scientific pursuit with a mind possessing that unusual degree of vigour, without which it is impossible both to resist the attraction of multiplied examples, and at the same time to overcome the obstacles that present themselves at the very entrance of a hitherto untrodden path. But let a new track be once struck out, and such is the fondness for novelty, that though it wander from the way to truth far more widely than the old one, yet forsaking this latter, almost the whole crowd will press forwards upon it. Thus it is, that both in the theory and in the practice of medicine, improvement is retarded by a slavish submission to authority on the one hand, and by an inconsiderate attachment to novelty on the other, qualities which, however opposite to each other they appear, are here, at least, closely united in their origin.

The truth of the above observations will, I think, be rendered sufficiently evident by a reference to that particular measure in the practice of medicine of which I am about to treat, namely, the use of purgative medicines. It is only a very few years since these were thought an essential part in the treatment of almost every disease. "The alimentary canal," it was said, "being the place in which the process of nutrition commences, it is absolutely necessary for the well-being of the whole system, that its functions be performed in a regular and healthy manner." Again, "the stomach and bowels, but particularly the former, are connected with every other part of the body by a sympathy so close and so powerful, that when a disease occurs, be its seat where it may, they cannot escape being more or less implicated in it." Now these arguments are just and reasonable; and the practice founded on them, restricted within due limits, was experienced

to be highly beneficial. But not satisfied with this, one or two persons, of considerable eminence in the profession, proceeded much further. According to them, not only is the alimentary canal affected in almost every disease, but it is from some derangement in its functions that most diseases originate. Entertaining this opinion, they regarded attention to the state of the stomach and bowels as the main, if not the only, curative measure indicated, no matter what was the nature of the affection, or where it was seated; and thus they framed a system of therapeutics which had, at least, the merit of being pre-eminently simple.

But this very circumstance ought to have rendered the profession wary in receiving it; for a remedy so simple and so general, implies simplicity and uniformity of derangement, a thing scarcely to be expected in a machine so complicated as the human frame is, both in its structure and its operations. Such, indeed, was the opinion respecting it entertained by many reflecting minds; but by the great majority of the public, both professional and otherwise, it was received, cherished, and maintained, with a zeal bordering upon enthusiasm. Every fact that militated against it was treated with contempt, or entirely overlooked; while all those which seemed to lend it support were brought forward, insisted on, and magnified in importance. Did you hear a physician belonging to this sect interrogate a patient? All his questions related to the state of the secretions, the frequency, the quantity, and the quality of the stools. The answers of the patient went, perhaps, to shew that here all was healthy and natural; but this was quite disregarded by the physician. He felt quite certain, whatever appearances to the contrary existed, that the stomach and bowels were the theatre of the first movements of the disease; or that they had become, at least, the head-quarters of its concentrated forces. To these parts, therefore, his operations were entirely directed. Blue-pill, calomel, jalap, and black-draught, were the instruments with which he worked, and he used them without much regard to moderation. Even of those who ridiculed the theory many soon came, almost insensibly to themselves, to adopt to its fullest extent the practice. Thus were all the

distinctive marks of diseases broken down; or if any were allowed to remain, it was only to divide them into two classes, those which admitted of violent purging, and those in which aperients only ought to be used. In this manner affections of the most opposite nature were treated with precisely the same remedies; and practitioners, so far from doubting the reasonableness of such a proceeding, prided themselves on their ingenuity in discovering, as they thought, the seat of the disease, when not a single symptom pointed to it.

Such was the method of practice which but a little time since prevailed throughout the profession. Now that the mania which established and extended it has passed away, we easily behold its extravagance; and wonder how, in opposition to reason and the evidence of well-known facts, it ever came to be so generally adopted. And yet if we examine attentively the doctrines respecting this part of medical practice, which are at the present day even more generally received and acted on, we shall, if I mistake not, find them to be still less consonant with reason and with truth.

It is a fact, unquestioned by the supporters, either of the reigning or of the deposed doctrine, that in a great proportion of the diseases to which we are subject, the mucous membrane of the intestines is more or less affected. The controverted point, then, is respecting the treatment of such cases; and here, if it be proved that the tenets of Hamilton, Abernethy, and their disciples, though confessedly extravagant, are nevertheless not only more consistent with reason and analogy, but are actually found to be more beneficial in practice than those of Broussais and the French school, it will scarcely, I think, be disputed that in adopting the latter we betray greater weakness of judgment than those did who put such implicit faith in the former.

It cannot have escaped the notice of any one who has been in the habit of reading the reports of cases treated in the French hospitals, that since the "physiological doctrine," as it is called, has come to be generally acted on, there have occurred a far greater number of instances in which ulceration of some part of the digestive canal has been the only, or the principal morbid appearance after death, than an equal number of similar cases ordinarily

present in the hospitals of this country, where such an extreme dread of purgative medicines has not yet seized upon the minds of the profession. Now it seems to me that this fact alone is decisive of the question; for I am not aware that there exists any other cause adequate to account for the difference; and, indeed, if we only reflect that in mucous membranes ulceration is a very frequent consequence of unchecked inflammation, and then consider the extremely inefficient method of treatment practised by the Broussain school, we will find it, I think, unnecessary to search after a different cause than this. What, for instance, can their lavements, their diluents, and their ptisans avail when violent inflammatory action has been established in the stomach or in the bowels? These measures, it is true, are aided by leeching and a pretty rigid system of abstinence; but, if I am not greatly mistaken, the application to the external surface of the abdomen of even a larger number of leeches than they usually have recourse to, cannot have a very powerful influence over the circulation in the internal parts; and the flame of inflammation, when once lighted up, does not require constant supplies of fresh food to maintain its existence; the system itself is almost always sufficiently well stored to furnish it with an adequate quantity of fuel. In what I here say, it is far from my intention to contend that abstinence, and the application of leeches, are measures altogether powerless. On the contrary, I am well aware that they are often very beneficial, but then they should be used merely as auxiliaries to other more efficient remedies, and not be trusted to alone, or in conjunction with means infinitely less active than themselves. I am not ignorant that, to the generality of persons, the application of thirty or forty leeches appears a very active kind of treatment; but in the particular affections of which we are treating, it exerts, in my opinion, by no means so powerful an influence. The grounds upon which I have formed this opinion are the following:—

1. The muscles and integuments of the abdomen, to which of course the application of the leeches is made, are principally supplied with blood by vessels which originate at a considerable distance from those furnished to the in-

testines, and which have very little connexion with them.

2. The slowness with which the blood moves through the intestinal capillaries, as well as through the portal system generally, and its tendency to congestion there, render them less easily affected by any diminution in the circulation than other parts much more remote from the place where the blood is drawn, and much less intimately connected with it.

This last objection, it may be urged, equally applies to the abstraction of blood generally, and I am ready to concede that it probably does. Where, then, are we to look for a remedy capable of achieving what neither of these measures, nor even both of them together, can properly effect? Before answering this question, which I expect to be able to do in the most satisfactory manner, I may remark here, that even in cases where the inflammation was of the most acute form, I have seen the application of a large blister succeed in checking it after blood-letting, both general and local, had been tried to no purpose. I can scarcely pretend to explain why it is that blisters should here prove so pre-eminently useful; but it may, in some measure at least, proceed from their rousing the capillaries of the intestines, and thus effecting a re-establishment of the suspended secretions. It is most probable, however, that had they been applied before the removal from the system of a proper quantity of blood, their effects would not have been so beneficial.

Having made these observations upon a practical fact, which is not, I think, in general sufficiently attended to, I proceed to state, in reply to the question above proposed, the means by which we have it in our power to effect what blood-letting, both general and local, fails in accomplishing. These means are simply the use of purgative medicines, by which alone we can hope effectually to relieve the overloaded intestinal vessels. Nor is there, as far as I am able to judge, the slightest cause for apprehending an increase of inflammatory action as the result of their operation. Unnatural vascular distention, if it do not itself constitute the inflammation, is at least a very prominent feature of it; and I have already shewn, that it is only by the use of purgative

medicines that that distention can be thoroughly removed. Indeed, the manner in which nature herself not unfrequently succeeds in terminating the disease by an increased secretion from the inflamed parts, indicates clearly enough the propriety of attempting, by similar means, to attain the same object. To this argument it may be objected, that there is a wide difference between the process by which this increase of the secretions is produced naturally, and that by which it is effected when artificial means are employed. But in this objection there is stated, as a positive fact, what is nothing more than conjecture, and conjecture, too, without any probable foundation in truth, for there is not the slightest reason to suspect that purgatives operate by exciting an action different from the natural one. They do nothing more than cause an increase of the natural action; and this is the identical process by which the disease is often spontaneously terminated. I am not here opposing mere assertion to assertion, for the effects in both cases are strikingly alike; and similarity of effect is a pretty sure proof that the causes are not very different.

I am aware that artificial purgation, to whatever extent it may be carried, will not, in many cases, succeed in arresting the progress of the disease; but neither does spontaneous purging invariably effect the same end; so that this circumstance merely goes to prove that vascular distention does not alone constitute the disease; but that, in addition to it, there is some other morbid affection (probably of the nerves of the part) which may continue to exist after the distention has been removed. But after all this, it may still be urged that active purgative medicines, though they produce merely an increase of the natural action, cannot but irritate the inflamed intestinal surface; and that such irritation must, of necessity, aggravate the affection. Now this is a question which could never be satisfactorily decided by mere theoretical reasoning, for scarcely an argument could be advanced on one side that might not be met with an antagonist one from the other. Let us look, then, to the facts furnished by experience, and see to what conclusion their evidence will lead us.

If it were my purpose to make a general attack on the doctrine of Brous-

sais, I could easily convict it of extravagance in supposing the presence of intestinal and gastric inflammation in numerous cases where no such inflammation really exists. Often and often have I seen tenderness over the stomach and abdominal region assumed as an undoubted proof that inflammatory action was going on in those parts when I had the utmost possible certainty that the tenderness was the result solely of the pressing and the pommelling which had been practised at a previous examination. But it is confessed, even by the most ardent supporters of the doctrine, that in many cases where they contend for the presence of inflammation, no sensible signs of its existence are afforded; while, at the same time, they cannot deny, that even in rude health, when the digestive functions are performed in the healthiest and most regular manner, the slightest pressure over the stomach will often be followed by a very keen sensation of soreness. These are facts which it is much easier to wink at than to meet with a successful opposition.

But the object which I hold in view is, to prove that even in those cases in which inflammation of the alimentary canal does really exist, the use of purgative medicines not only is not pernicious, but is actually productive of better effects than any other measure that we can have recourse to. And here I shall adduce a single fact, which, if the above observation be not strictly true, appears to me utterly inexplicable. In *enteritis*, attended with constipation, the general practice, at least in this country, is, after a due abstraction of blood, to throw in the strongest purgative medicines, almost without any regard to quantity, till several evacuations have been procured. And so far is the operation of these medicines from proving pernicious, that until it has taken place to a considerable extent, the patient cannot be considered free from danger. If it be objected to me, that in such a case as that to which I have alluded, there are hardened feces, which act as a mechanical obstruction, irritating the parts, and that the utility of purgatives consists in their procuring the expulsion of these, I answer that the objection does not very much affect my argument; for it is inflammation that constitutes the disease, of which the constipation is, in general, but a mere

symptom; yet we find that copious purging is the most effectual remedy for it, the principal use of the different other measures, blood-letting itself not excepted, consisting in their disposing the intestines to be more easily acted on by the purgative medicines. But even though I were to concede that in every case of enteritis the obstruction precedes the inflammation, and is the cause of it, my argument would still, nevertheless, hold good; for in *enteritis*, inflammation, by whatever cause excited and maintained, must be allowed to exist; and yet it is not aggravated by purgatives, but, on the contrary, is more relieved by them than by any other remedies. But it has been contended, that in *enteritis*, attended with constipation, the disease is entirely, or for the most part, seated in the serous membrane; so that in it purgatives cannot by contact irritate the inflamed surface. Now if it were true, that in this disease the serous membrane is exclusively the seat of the inflammation, the above reasoning might, perhaps, be admitted; but as morbid anatomy proves the case to be otherwise, its rejection ought not, of course, to cost us a moment's hesitation.

Another argument, proving unanswerably the utility of purgative medicines in inflammatory affections of the bowels, may be derived from the benefit following their use after the operation for strangulated hernia. It is the practice with most experienced surgeons to get the bowels thoroughly opened as soon as possible after the intestine has been reduced; and when this has been once effected, the danger of the patient is considered to be greatly diminished. This is a fact which will scarcely, I think, be disputed; and, as in all cases where the strangulation has existed even for a few hours, there must necessarily be inflammation, I cannot possibly see how the Broussais could attempt to explain why that inflammation is not aggravated by the purgatives.

The utility of large doses of calomel in the various dysenteric affections, so common in tropical climates, is rendered unquestionable by the concurrent testimony of Johnson, Annesley, and a whole host of other witnesses, many of them scarcely less eminent than these for closeness of observation and correctness of judgment. Now that these affections are of an inflammatory na-

ture; that, in fact, they consist essentially in indammation of the mucous membrane of the alimentary canal, scarcely admits of a doubt. How, then, does it happen, that in them calomel, so irritating in its nature, so drastic in its operation, and therefore so peculiarly the horror of Broussais and his disciples, proves beyond all comparison the most useful remedy with which we are acquainted? Whence, too, is it, that within certain limits, its good effects are more and more conspicuous in proportion as a larger dose of it is given. According to the "physiological doctrine," every increase in the quantity administered ought to produce a proportionate increase in the severity of the symptoms. The very reverse, however, of this is, as has been already observed, what really takes place. Small doses, by augmenting vascular action, without carrying it to such a height as to produce copious secretion, only torture the disease, which, out of resentment, as it were, for the injury done to it, always assumes additional violence, and not unfrequently succeeds in demolishing the fabric which contains it; while a single large dose is often sufficient to strangle it on the instant.

In the catarrhal affection which prevailed so generally throughout the country a short time since, I had numerous opportunities of proving the truth of the opinion for which I am here contending. The gastro-pulmonary mucous membrane, including, of course, that which lines the nostrils, mouth, and fauces, was the part principally affected. In general the symptoms were not very severe; yet there were some cases in which there prevailed excessive vomiting and purging, with violent internal pain, as well as external tenderness. Here, then, were symptoms the most unequivocal of inflammation—and inflammation, too, of rather an acute nature; and yet the cases in which recovery took place soonest were those that had been treated, from the commencement, with extensive purgation. Six or eight grains of blue pill at bed-time, with a drachm of compound jalap powder on the following morning, universally succeeded in ameliorating the symptoms. Repeated once or twice, with merely an antimonial powder, or draught, given occasionally in the intervals, they seldom failed in effecting a cure. In general, half a grain or a grain of opium

was administered with the pill, both to ease the pain and to pacify the stomach, which was irritable and averse to retaining the medicines.

Contrasted with the success of this method of treatment, that of the Broussaian plan, which was tried in a few similar cases, shewed poor in the extreme. In these cases, the purging and vomiting, together with the pain and sickness which accompanied them, instead of being soon considerably mitigated, or of ceasing entirely, as usually happened after the operation of the purgative medicines, continued day after day, exhausting the patient, till at length nature succeeded in effecting, by a copious secretion from the intestines, what the exhibition of one or two smart purgatives might have easily accomplished on the first or second day after the attack. It is scarcely necessary for me to add, that when the disease was thus allowed to run its course, it left behind it a degree of debility, particularly in the digestive organs, which was not recovered from till after the lapse of a considerable period of time.

JOHN M'DIVITT.

Kegworth, Oct. 24, 1831.

BOTANY OF NEW ZEALAND;

BEING A

Description of Trees, Plants, &c. indigenous to that country.

By GEORGE BENNETT, Esq. M. R. C. S. &c.

[With Engravings.]

THE vegetable productions of New Zealand are very numerous. Among the lofty timber trees which adorn the New Zealand forests, the "Pines" are the most conspicuous, from their stately, erect, and elegant growth: in the form of plank and spar, they are an article of commerce between that country and the colonies of New South Wales and Van Diemen's Land, and profitable voyages have been made with a selected assortment of spars even to England. I am acquainted with six New Zealand pines, and have specimens of them in my Botanical collection: they bear the native appellations of Kowri, Remu, Tánakáá, Káwaka, Tótara, and Kái-

kea-tea, the whole of which are found growing on elevated land and in good soil.

The timber produced from the New Zealand pines varies in quality: the Kowri is generally preferred for the yards and masts of ships, as well as for other purposes; the Tánakáá is much heavier than the Kowri, sinks in the water, and is not very durable. It has been stated that the spars brought from New Zealand have been found on trial to be of equal gravity with Riga spars, and to possess a greater degree of flexibility than the very best species of fir procured from the north. The wood of the Kowri is much finer grained than any timber of the pine tribe; and the trunks are of such a size as to serve for the main and foretop masts of the largest three-deckers. The Prince Regent, of 120 guns, is supplied with them: they have also been used in sea-going ships, and the reports of their qualities are most favourable*.

Among other timber trees are the Knightea excelsa, with its clusters of beautiful crimson flowers; the Edwardsia microphylla, with its pendant golden blossoms; the Puredi (Ephialis Sp.), Pohu-tukawa (Metrosideros Sp.) &c. &c. Ferns abound in the New Zealand forests, among which may be recognized the genera Polypodium, Trichomanes, Lycopodium, Cyathea, Asplenium, &c.; the beautiful Todea pellucida of Brown, Trichomanes reniforme, Lindsia trichomanoides, &c.; and on the declivities of the hills, a beautiful species of Astelia, flowering in May, June, and July, is found very abundant. A great variety of the mosses and fungi are found also in the New Zealand forests, the latter attaining very large dimensions.

Dammara Australis, LAMBERT.

Dammara RUMPHIUS.

Agathis SALISBURY.

Kowri of the natives of NEW ZEALAND.

Natural Family, *Coniferae*.

This magnificent tree is an ornament to the New Zealand forests. It is the *Agathis* of Salisbury, the *Dammara Australis* of Lambert, and is named

* Quarterly Review, vol. xxxi. p. 64, Dec. 1824.

Kowri by the natives of New Zealand, which name, it is said, was given on account of the great diameter it attains. It grows very erect, and attains the height of from eighty to ninety feet, and in diameter is considered the largest tree in New Zealand. It is said to attain twenty-four feet in circumference, and I have seen several cut down measuring from sixteen to twenty feet. The timber is of an excellent quality, close grained, durable, and valuable for a variety of purposes, either in plank or spar: as yards and masts for shipping, they have been found, by repeated trials, superior to all others, both in their flexibility as well as durability. The wood is of a white colour.

The leaves, when young, are alternate, but in form lanceolate, which change, as the tree increases in growth, to an elliptical or oblong form.

This tree yields a great quantity of resin*, of a white or amber colour, very transparent, burning with a bright flame, and having a very agreeable smell. It exudes spontaneously and concretes on the trunk, but an incision being made in the tree and left for a night, on the following morning a large quantity is found to have exuded, which continues still to exude from the incision for a long time afterwards. This tree yields the largest quantity of resin of all the New Zealand resiniferous trees. It resembles the resin named Dammar in the East Indies, and is, indeed, produced from a tree of the same genus, and might consequently be employed for similar purposes for which that resin is used in India—as a pitch for ships, &c. &c.; and might form an article of commerce from New Zealand to the colonies of New South Wales, Van Dieman's Land, &c.; and, from the quantity I have seen exude from one tree, it may be collected abundantly in a short period of time. The natives name the resin the Wai (Wy), or water of the tree.

The pigment, or soot (Ngarahu), which is the colouring substance used by them in the operation of tatauing, is usually prepared from this species of pine, from its possessing more resin than any of the others. The manner of

preparing this soot among the New Zealanders is as follows:—

An oven is formed of stones, in which a fire is made of the wood of the pines, but more usually of the Kowri pine; from this a soot collects on the roof, and after sufficient quantity has been collected the fire is extinguished, and a mat being placed at the bottom of the oven, the soot is scraped off the upper part and collected in the mat placed underneath. It is then placed into a vessel, and sufficient water added to form it into lumps; in which state it is preserved until required for use. The soot yielded by this process is of a fine black colour, and a gum resin (damuh) is also used by the Javanese, which, being burnt and the soot collected, is used by them in the manufacture of their ink, which is beautifully soft and black, and is said probably to equal, in most respects, that of the Chinese. Our process of obtaining a lamp-black* is not far different from that adopted by the savages of New Zealand, and it is the resiniferous among trees that yields the most beautiful lamp-black.

When I inquired of a New Zealander, why they did not use any other kind of tree, and why particular pines were preferred? his reply was, because the pines contain more Wai (Wy), or Resin; and the Kowri was preferred because it contained more than any other species. When Resins burn they yield a quantity of smoke, from which much soot is deposited; this was observed by the savage, and adopted as an opportunity of acquiring a pigment for adorning his person. Among savages I have invariably found a very intimate knowledge to exist of trees, plants, &c. and the various uses to which they were capable of being applied†. The natives of New Zealand

* Thus mentioned by Dr. Maton, in Lambert's work on the Genus Pinus. "A sort of box is made, nicely closed in every part, with the exception of some holes on the top, which are covered with a sort of linen cone. At a little distance from the box a furnace is constructed, with a very small mouth, and the inferior part communicating with the inside of the box by an horizontal chimney. Into this furnace are put the dregs and coarser parts left in the preparation of tar; and in proportion to the consumption of these a supply is kept up, so as to furnish a constant draught of smoke into the box. The smoke goes chiefly into the cone, when it deposits its soot, or lamp-black, which is employed almost exclusively in printing and dying."

† The black pigment used for tatauing at Tahiti, is procured from the nuts of the Tiari, or Candle nut-tree (*Aleurites triloba*), and also at Tongatabu

* Vae is the term used in the New Zealand language for the Gum-resin; it also signifies the gum which exudes from the eyes. Wai (Wy), or water of the tree, is also used.

also collect the resin of the Kowri tree and use it as a masticatory, similar to a curious bituminous substance, a kind of Asphaltum (with a smell of Naptha), named Mimiha*.

There is a magnificent coloured engraving of this tree in Lambert's splendid work on the Genus Pinus; but it is to be regretted that the expensive style in which that work is published renders it almost inaccessible to the botanist, and consequently renders it less useful to science.

Knightea excelsa—BROWN, Lin. Trans. vol. x. 1811.

Riwa-riwa of the natives of NEW ZEALAND.

Natural Family, *Proteaceae*.

This tree is abundant in the New Zealand forests, and is named Riwa-riwa by the natives; it is more usually found growing on the declivities of hills. It is a handsome tree, and attains the height of from sixty to seventy feet, but seldom exceeds more than seven or eight feet in circumference. The trees that came under my observation were invariably straight in their growth. The timber is of an excellent quality, but, on account of its small diameter, is not cut into plank, but is used for making planes, &c. by Europeans. The flowers are of a beautiful crimson colour, and the capsules are of a dark brown colour, growing in bunches of from twenty to thirty, each capsule containing from four to six winged seeds. I collected several specimens of this tree (with the capsules in a mature state) at Wyshaki Cove, River Thames, New Zealand, in June 1829. A branch of this tree is figured in the Linnæan Transactions, vol. x. 1811, both in flower and fruit, but the mature seed has not been delineated.

THE HOROEKA TREE OF NEW ZEALAND.

This tree, curious in form and its mode of growth, has not yet been ob-

served by botanists either in flower or fructification. During a diligent search during the months of April, May, June, and part of July (1829), although I collected nearly a hundred specimens (thirty of which I brought to England), I was unable to procure it in flower or fruit. It is found growing usually in shady situations, on elevated land, as well as in vallies, and in good soil: it attains the height of from twenty to forty feet. In the very young trees the leaves are scattered; but in those which have attained more maturity and elevation, the leaves become tufted. No branches are thrown out, unless a short stalk, from which the tufts of foliage arise, can be so named. The leaves are about a foot in length, and an inch in breadth, and are irregular at their edges, and abrupt at their terminations, of a dark green colour above, the centre stalk being of an orange colour, and underneath the leaves have a brownish-red tinge.

In young as well as in more mature specimens, I have observed a change in the form of the leaf, on some the whole of the foliage being *ternate*, on others some of the leaves only being *ternate*, and others being of the usual form; others again have *ternate*, *biuate*, and *single* leaves, on the same tree. This anomaly was more usually observed on young specimens than in mature trees.

The leaves on the summits of those trees which had attained a great elevation, became of increased breadth and decreased length; but this was not confined to old trees, young ones often exhibited similar anomalies in their foliage*. Some of the trees grow very erect, others bend towards the ground.

Some of the trunks of trees that I measured were only a foot to a foot and a half in circumference at the base, although in height they were thirty feet and upwards. The wood is very close-grained and flexible; and some Europeans residing at New Zealand informed me that they used it in boat-building. The accompanying sketch, taken from a recent but young specimen, will show the peculiar form of the leaves; (a) the *ternate* leaf.

from the nuts of the same tree, where it is named Tul tul. At the Island of Rötuma, from the nuts of the Fifiu (*Calophyllum inophyllum*). All of these nuts contain oil. The nuts are first baked to a charcoal; afterwards pulverized, and mixed with oil.

* An account of which was published in the Medical Gazette of June 4, 1831, vol. viii. p. 392.

* It was at Wyshaki, river Thames, that the principal opportunities were afforded me of observing the growth and changes of foliage in this tree. Although I observed numerous specimens in a valley near the watering place at Kororadeka, Bay of Islands, I did not observe the anomalies in the foliage at that place.

Since writing the preceding I have been informed that a specimen in fructifica-

tion has been procured at New Zealand by one of the missionaries, and sent to Mr. Cunningham at Sydney, who has since brought it to England; we may therefore expect a description of this curious tree from that able botanist, and learn to what natural family it belongs.

OBSERVATIONS ON HERNIA.

To the Editor of the London Medical Gazette.

54, Stamford-Street, Oct. 24th, 1831.

SIR,

IN the Medical Gazette for February 19th last, there are some observations on hernia by Mr. Lizars, in which he has done me the honour of quoting my opinions; but as he appears to me to have misconceived the real nature of those opinions, I trust that it will not be deemed otherwise than an act of courtesy to him and your readers, to communicate (through the medium of your journal) a further explanation of my views upon the subject. I should have done so earlier, but other matters diverted me from the purpose.

Mr. Lizars commences by testifying to the difficulty in deciding upon the propriety of operating, and to the difficulty of diagnosis and prognosis, in cases of hernia. His words are, "there are four species of hernia which, in my opinion, demand an operation, viz. the acute or inflammatory strangulated, the slow or chronic strangulated, the incarcerated hernia, and the obstructed hernia." With due deference to Mr. Lizars, I conceive the whole difficulty in understanding the nature of hernia arises from the multiplicity of names used by surgical writers without any adequate or proper idea attached to them. I believe that if the terms, strangulated hernia, chronic strangulation, incarceration, engouement, &c. were abandoned, it would conduce to a better understanding of the subject. For example, all the symptoms which are said to denote a strangulated hernia, may exist without any strangulation, or even without any stricture whatever; such symptoms being common to all mechanical obstructions of the bowels, whether from adhesion of the intestine, intussusception, or to a contraction of the calibre of the canal, and by no means peculiar to strangulation. The

term slow, or chronic strangulation, only applies to a state of constriction *not amounting to strangulation*, and is therefore incorrect. Incarceration conveys no idea beyond that of irreducible hernia: it does not express the morbid condition (obstruction) to which an irreducible hernia is subject. Engouement also is but the name for an effect: it does not express the cause of the disorder. Whence arises the engouement, or accumulation, but as an effect of some cause impeding the action and passage of the bowels? Engouement is, therefore, the *effect* of obstruction.

We should consider hernia first in its simple state, hernia meaning a simple protrusion; second, in its obstructed state, obstructed hernia meaning a hernia affected by some cause obstructing the function and passage of the intestinal tube. If the cause is stricture, the symptoms will be more or less acute and violent, depending upon the greater or less degree of constriction, and this may very properly be called acute obstructed hernia. If the cause is a confinement of the intestine in an unfavourable position, *without any stricture*, whether from adhesion, or from the intestines being in too narrow a space to carry on their peristaltic action, or transmit their contents, the symptoms, although the same in kind, will be more mild and protracted, and this will be properly defined by the term subacute obstructed hernia. The term obstructed hernia expresses the morbid condition, obstruction, under which a hernia, when requiring an operation, labours. The terms, acute and subacute, attached, express the *different degrees* in which they are affected. The only other term, in my opinion, which need be applied to hernia, is that of inflamed hernia, which term I have, in my Treatise on Obstructed and Inflamed Hernia, &c. given to denote a state of inflammation among the contents of a rupture, independent of any direct mechanical obstruction, but arising as a consequence of the morbid changes which the parts undergo from long protrusion.

I cannot but dissent from the opinion of Mr. C. Bell, quoted by Mr. Lizars, that "the obstruction kills by the violence of the inflammation, occasioned by the accumulation in the upper parts of the canal, and the violent workings of the muscular coat of the intestines."

The obstruction kills by the stoppage of an important vital function without the necessary intervention of any inflammation, as I have proved in the Treatise I have published, and which will be still further proved in an appendix to a forthcoming edition. Mr. Lizars has quoted from my book a passage commencing, "the character which the disease assumes is that of peritoneal and general inflammation," &c. The above passage Mr. Lizars has quoted as a part of my description of obstructed hernia. This is an oversight, such passage belonging to the description I have given of inflamed hernia, a state of the intestine particularly distinguished from obstructed hernia; I having also particularly stated that inflammation among the intestines is by no means a necessary consequence or attendant upon obstruction.

Requesting an early insertion of the above, I am, sir,

Your obedient servant,

HENRY STEPHENS.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tînt à allonger ce que le lecteur se tînt à abrégier."—D'ALEMBERT.

The History of the Contagious Cholera; with Facts explanatory of its Origin and Laws, and of a rational Method of Cure. By JAMES KENNEDY, Member of the Royal College of Surgeons, London.

IF we were disposed to pay Mr. Kennedy an ambiguous compliment, we might recommend his volume as the most convincing in itself, and the most satisfactory that we have met with for some time. The contagious character of cholera is here clearly proved, from the facts stated; and the treatment, of which the author approves, is fully borne out by the cases adduced. The professions of the title-page are largely fulfilled; and as the book is meant to be intelligible even to unprofessional people, we think the author may congratulate himself on having accomplished his object. The reader has but to be persuaded that here is the *whole* history, and here are *all* the reports worth giving, and nothing can be more conclusive than Mr. Kennedy's labours.

205.—1x.

But, unfortunately for us, we have dipped rather too deeply into the sea of evidence, in the shape of multiplied reports, despatches, and official documents of all sorts and sizes, to permit us to be so easily satisfied, or to come from the perusal of the work untinged with some remnants of scepticism. Our pages, for months past, have shewn how much attention we have bestowed on all that was to be said on both sides; and though, to confess the truth, we are strongly inclined to adopt Mr. Kennedy's view of the question, to which we think the balance of the evidence will be found to preponderate, yet candour forbids us to declare ourselves perfectly satisfied as yet, and our duty as reviewers obliges us to remain unwedded to any particular set of opinions. This, however, by no means prevents us from appreciating the straightforwardness with which our author hoists his flag and announces the party to which he belongs. Mr. Kennedy, in fact, spends little time in reasoning directly on the contagiousness of the cholera; his historical matter and his collection of reports are arranged with sufficient ingenuity to carry the desired inferences along with them; and he is willing, he says, to consider the two following general facts as amply sufficient to justify his views:—

"The first is connected with the local progress of the disease, as when it begins in a camp or a town. Here, its first appearance is announced in the attack of one or of a few individuals, and the number of the cases gradually increases. This course cholera has universally pursued. Now, had the cause of the disease been generally diffused in the atmosphere of the camp and town, would not great numbers of the people have been attacked, almost immediately, on the occurrence of the first case?

"The second general fact is the following:—Among the islands of the Indian Ocean, it was observed that the cholera uniformly commenced its ravages in the sea-port towns, or in those towns seated a few miles inland, which have a constant intercourse with their harbours at the shore. In the island of Mauritius, the disease first appeared in the town of Port Louis. In Bourbon, the town of St. Dennis was the first attacked. In Java, the town of Samarang, and so of the islands Sumatra, Penang, Borneo, Celebes, Lucon, &c.

M

In the Persian Gulf, also, the same order of infection was observed. Muscat, the principal trading port town, first received the disease. Then the port of Bahrein, and Busheer and Bassora. How can this extraordinary and uniform partiality which the cholera exhibited in its choice of sea-port towns for its first inroad be explained, unless on the principle of imported contagion?"

It is to be particularly noted, that by far the largest portion of the volume is occupied with the history of the *Indian cholera*, and the principles and mode of cure which the author adopted when he was out in Hindostan. The disease, as developed in Western Europe, Mr. K. seems to think is identically the same as the Indian disease; nor does he seem to consider that the treatment, by rigorous depletion and dosing copiously with calomel and opium, so familiar in Indian practice, should be in any degree modified in the management of cholera among ourselves. Upon this subject we have more than once expressed our decided opinion, nor need we repeat our reasons, founded upon experience and the strongest testimonies, for deeming that herein lies Mr. Kennedy's most essential faultiness. We doubt not, however, but that most readers will make this observation for themselves: were we but sure of it, we should have no hesitation in recommending the volume generally, as one of the most interesting on its awful subject that has yet fallen into our hands.

The work is furnished with two maps, from which we copy the following dates of first visits of the cholera:—

Jessore and Calcutta	Aug. 1817
Delli.....	July 1818
Bombay	Aug. —
Madras.....	Oct. —
Palamcottah	Jan. 1819
Manilla and Canton	— 1820
Pekin	— 1821
Busheer, Shiraz, Yezd, and Ispahan'	— —
Indian Islands.....	— 1823
Orenburg	— 1829
Astracan (up the Volgar) to Moscow	July to Sept. 1830
Down the Don to Azof, Sept. to Oct.	—
Warsaw	April 1831
Dantzic and Riga	May —
Archangel and Petersburg, June	—
Pesth and Bucharest	July —
Berlin	Aug. 31, —
Vienna	Sept. —

Between the years 1823 and 1830, Persia seems to have been the *nidus* in which the slumbering pest was kept alive, and from which it got into Europe through the port of Astracan.

Reports of Medical Cases. By DR. BRIGHT. Price 9*l.* 9*s.*

[Continued from page 88.]

PRESSURE ON THE BRAIN resumed.

Obstruction in the Lungs.—The next source of pressure on the brain adverted to by Dr. Bright is obstructed circulation through the lungs.

A bulky gentleman, above 70, who for several winters had been subject to chronic bronchitis, consulted Dr. Bright. He was in his drawing-room, walking about, but talking frequently; knew the doctor when he entered, and answered some questions about his health coherently; then at once seemed to become forgetful, and talked wildly. His attention, however, was immediately recalled, but as speedily was gone again. The pulse was large and full, about 80; the tongue dry, brown at the centre, and white towards the edges; the cough gave him great pain in the forehead; his expectoration was copious. Under the use of calomel, with purging mixture, ipecacuanha, and blisters to the chest, he was completely restored in a fortnight. Another case, however, which was very analogous, did not end so favourably. When Dr. Bright was sent for his patient was sitting up in his drawing-room, dressed as usual; his countenance was dusky, and his lips and tongue purple; he answered questions rationally for a few moments, and then became incoherent; his breathing was very difficult, and he complained much of weight at the chest; his pulse was large. He was cupped to eight ounces on the pit of the stomach, and had expectorant medicines; but he continued to get worse, and died early next morning.

We confess that both the above cases seem to us rather to shew cerebral disturbance from the circulation of imperfectly arterialized blood than from pressure.

A man, aged 46, was admitted into Guy's Hospital with dyspnœa, cough, and abundant expectoration of frothy mucus; his shoulders required to be elevated; his extremities were cold and œdematous; his pulse feeble and irre-

gular. Stimulants were administered, but he grew more and more oppressed, and died within two days. On examination after death, general turgescence was found in the vessels of the brain, with a peculiar mottling throughout the whole medullary substance, which became still more conspicuous when a slice was cut off, and allowed to become dry. The lungs bore marks of old inflammation, and the mucous lining of the bronchi was red, thickened, and in places even granulated.

Several cases follow in which cerebral congestion arose from emphysema of the lungs. In these cases the clear hollow sound emitted by the chest on percussion, and the faint murmur of respiration which was present at the same time, clearly indicated the nature of the disease. The head affection, however, presents nothing peculiar, under such circumstances, to distinguish it from others dependent upon imperfect action of the lungs. In the two cases which follow, great congestion in one, and actual extravasation of blood on the surface of the brain in another, were dependent upon whooping-cough. Yet farther instances are given of congestion of the brain, brought on by pulmonary obstruction; but the illustrations we have given will be sufficient on this head. We observe that Dr. Bright attributes the symptoms to the joint operation of mechanical congestion and a chemical change in the blood.

Pressure from Serous Effusion, independent of Inflammation.

This constitutes an entirely distinct pathological condition from any of the preceding, and the first case adduced is one in which the cause must be regarded as entirely mechanical. A woman was hanged, and the brain examined forty-eight hours after her death. Drops of fluid blood presented themselves on the surface of the dura mater and on the inner surface of the bone, which had a mottled appearance from effused blood. There was no coagulum in any of the sinuses; there was "decided, but not great" serous effusion under the arachnoid; the medullary substance of the brain was of a dusky colour, and full of bloody spots; the ventricles contained some serous effusion; the vessels at the base of the cranium by no means injected;

the arteries, indeed, were empty. In this case the appearance of cerebral congestion was not nearly so great as in some of the pulmonary affections above detailed, and not nearly so well marked as in the cases of death by hanging published some years ago by Dr. Monro, of Edinburgh, and by the late Dr. Kelly, of Leith.

Four cases are next detailed in which persons had become insensible from breathing the fumes of burning coals. They had all well-marked symptoms of cerebral congestion, but two of them recovered. In the two who died, slight serous effusion was found beneath the arachnoid, and there was some, but not considerable, appearance of increased vascular turgescence. In the case which follows next in order, effusion had taken place into the ventricles and beneath the arachnoid, from vascular congestion dependent on diseased heart. In another the same effect resulted from bronchitis; and in a third, which was attended with apoplectic symptoms from serous effusion, the kidneys were found granulated. In this case the urine was coagulable. The same appearance—namely, effusion of serum beneath the arachnoid, also presented itself in several cases of anasarca, where the kidneys were granulated, and the urine coagulable.

In case 118, a weak exsanguine man, with tuberculated lungs, had effusion under the arachnoid; in case 119, the same occurred in a case of emaciation, with bilious vomiting; and in three cases of diabetes, the only instances in which Dr. Bright has examined the brain in that disease, serous effusion was discovered. The author concludes this section with the following remarks upon the cases which it contains.

"In the foregoing cases of serous effusion we have an opportunity of tracing several of the different circumstances under which this morbid affection takes place within the cranium, independently of inflammatory action. These circumstances, for the most part, are immediately and obviously connected with a state of congestion, from causes which either act to a certain degree mechanically, or produce a state of debility which favours the irregular accumulation of blood. In the first case, direct mechanical pressure was applied; and if, as we suppose, the effusion depended upon the congestion arising

from the ligature, the effect must have been produced very speedily. This, however, accords with what we have reason to believe occurs occasionally in disease, where, from the rapid appearance of symptoms, effusion seems to have taken place within a very few hours before death. Some facts have been recorded by Dr. Kellie which shew that causes producing cerebral congestion are calculated to bring on very speedily serous effusion: he has related the cases of two individuals who were found dead from a night's exposure to cold, where serous effusion had taken place to a considerable extent, both in the ventricles and beneath the arachnoid. The well-known effect of cold in producing a state of unconquerable drowsiness, is satisfactorily explained, if any such elucidation were requisite, by these two cases; for excessive venous congestion was found accompanying this effusion, and it is this state of congestion, no doubt, which brings on the lethargic slumber, and terminates in effusion, or not, according probably to the previous condition of the sufferer.

"The five cases in which symptoms of cerebral congestion depended on inhaling fumes from coal and from the brick-kiln, afford further examples of the same tendency to serous effusion when the circulation through the brain is obstructed; for in the two cases where death unfortunately gave us an opportunity of investigating the state of the brain, serous effusion had actually taken place; in most of the others there is reason to believe that the morbid affection proceeded no further than the state of congestion, though it is not impossible, from the slow recovery in Case CVII., that effusion had actually taken place to a small extent.

"We have likewise, amongst the cases of serous effusion, an example in which the congestion depended on the circulation being obstructed in the heart, a circumstance which is by no means uncommon; there are others in which bronchitis and phthisis, by permitting the natural flow of blood through the lungs, have produced such a condition in the vessels of the brain as has led to serous effusion: frequently, indeed, as we have before seen, these same causes of obstruction produce only venous congestion, a difference which depends upon the previous condition of the body. In some cases simple debility

is perhaps capable of producing this effect, of which phthisis and diabetes seem occasionally to afford examples; though in both of these, other causes are brought into action, besides debility, in a manner likely to favour the effusion. We have sometimes less questionable examples of this cause of serous effusion, afforded in hæmorrhagic diseases and in the exsanguine constitutions of anasarcaous patients, though in a great majority of these cases decided affections of the kidney, or of some other important organ, as the spleen, serve to throw doubt upon the extent to which debility should be considered the prevailing cause of the effusion."

Pressure from Effusion of Blood within the Cranium.

A very interesting and instructive collection of cases follows. They may be divided into those in which the effusion had taken place on the surface, and those in which it had occurred in the substance of the brain.

A diminutive lad, aged nineteen, was visited on the 30th of November; he was lying on the bed insensible, with the breathing slightly stertorous. He had complained of being unwell; and while on the close-stool suddenly exclaimed, "Oh, my head," at the same time laying his head on the bed. In this state he had continued till the time of being seen by the narrator, (Mr. Streeter). The pulse was jerking, and the skin moderately warm. A vein was opened, but ere two ounces had flowed he became cold, and the pulse fluttering; the arm was instantly bound up. Some brandy, and a little compound spirit of ammonia, were administered; cloths, dipped in warm water, were applied to the pit of the stomach; and as the head felt hot, cold cloths were applied suddenly, and with a jerk, (as a substitute for cold affusion, and to avoid wetting the bed) to the temples. As no abatement of the insensibility took place, two cupping-glasses were applied to the back of the neck, but without previous scarification. Still no apparent improvement manifesting itself, one scarification was made, and about an ounce of blood abstracted—watching its effect on the pulse, which becoming depressed, the depletion was immediately discontinued. After a few hours he regained his sensibility, and was able to speak, though languidly.

He was blistered on the back of the neck, and purged; and he appeared gradually improving till the 8th of December, when he had a return of pain in the head; during the night he became insensible, and died at eight next morning. Dissection exhibited at least eight ounces of blood on the left hemisphere of the brain, and this was found to have proceeded from the bursting of an aneurism, about the size of a small bean, where the anterior and middle lobes join: it was connected with one of the smaller ramifications of the middle cerebral artery.

A lady, advanced in life, suffered a sudden attack of apoplexy in May 1827, but which was so entirely relieved by bleeding that in a few days she was free from any symptom of it except slight headache. In February 1828, having dressed as usual, she fell down on walking into her drawing-room. She was bled, and recovered a little, so as to complain of excessive pain by screams and moans, but she could not speak, and died in about half an hour. No trace of the former attack was found on examining the head. Blood was effused deep between the convolutions of the brain, particularly on the left side. There was some blood in the third ventricle; none in the others. The rupture was supposed to have taken place where the vena magna Galeni joins the lateral sinus; near that part the chief coagulum was situated.

A gentleman fell and received a blow on the back of the head, not sufficient to excite much attention, though it caused some external tenderness. Some days afterwards he dined out, and on the following day had a party at home. The morning after, he complained of pain in the head, became sick, and on the third morning suddenly lost the use of the left side, and could scarcely articulate. He was bled copiously, but died in the evening. On the posterior surface of the right hemisphere was a large quantity of blood. Serum was effused in other parts of the brain, and also in the spinal canal.

A gentleman, aged 72, fell down while walking, having tripped against some wooden pegs, on one of which he struck his face. His nose bled very freely, but he got up and walked home, three quarters of a mile, and called on Mr. Estlin, of Bristol (by whom the case is related), on his way. No injury of any kind, except

the bruise on the face, could be detected. He was purged, a cold lotion applied, and he was ordered to keep quiet and abstain from wine, &c. He continued, however, to walk about, as well as to eat and drink as usual. Mr. Estlin then adds—

“On the 11th of May (twelve days from the fall) he was met by his daughter, walking *from* his own house; and on being asked whither he was going, said he was proceeding *homeward*,—and shewed other marks of loss of judgment. I saw him soon after his return, and found him in a confused state of mind, with some incoherence. He occasionally fell off into a sort of doze; and asked if I had been sent for, and had returned any answer? at the time I was sitting by him. He frequently took up a book and appeared to read; he complained of his head, but did not express any sense of severe pain. He walked with difficulty up to bed (two stories): I bled him, and purged him freely; the bowels were much loaded, and were torpid. On the following day some paralysis of the limbs appeared, and rather violent spasms of the face, particularly of the muscles of the lower jaw and neck, coming on in paroxysms, and lasting for a minute: his speech became very inarticulate, and he dozed a great deal. The symptoms daily increased. He was blistered, leeches, &c. When asked if in pain, he always said, “No;” and seemed, when thoroughly awake, conscious of what was said to him. His pulse was not quick or unsteady, and the pupils were not in any respect dilated. He died on the 18th of May.”

On sawing through the cranium, a copious bleeding took place on the right and anterior part of the skull. When the calvarium had been removed, much coagulated blood was discovered beneath the dura mater, which extended to the base of the middle lobe, and invested the origin of the fifth pair of nerves. No injury of any part of the bone could be detected. The ethmoid was particularly examined. The source of the hæmorrhage could not be made out. Mr. Estlin thinks that the effusion was gradual.

A tall, large-made man, aged 46, of rather intemperate habits, and of gouty diathesis, had had at different times, some years before his death, fits of giddiness, pain in the head, and other cere-

bral symptoms, together with a peculiar fluttering sensation about the heart. About six months before his admission, he had a fit of an epileptic character, which occasionally returned; and he appeared, about two years previously, to have had a paralytic affection of one side of the face. His pulse was seldom above 30, and sometimes fell to 22. He had been in the hospital for gout during some months in the autumn of 1828, when he had frequent fits of palpitation, with confusion in the head. In May, 1829, he was again admitted, labouring under a similar condition. One of the most remarkable symptoms above alluded to continued—viz. the slowness of his pulse, which now averaged 32, while his respiration was so much as 28. He again left the hospital on the 1st of September, returned next day in his usual state for some mixture which he was in the habit of taking, and on the 3d, while in the act of taking a glass of spirits, he uttered an exclamation, fell, and died without a struggle. The following remarkable appearances were found in the head, which, we ought to remark, was not examined till five days after death.

“On raising the anterior lobes from the skull a very marked black appearance was observed on the inside of the dura mater, covering the bone on each side of the crista galli: it was evidently a carbonaceous deposit in the layer of arachnoid lining the dura mater, and was made up of a number of black points: this black colour increased greatly in intensity on all that part of the dura mater which lines the petrous portion of the temporal and the lower part of the parietal bones, and proceeded quite back to the tentorium, and was observed likewise on the dura mater of the occipital bone, almost to the foramen magnum; and although chiefly on the right side, passed over slightly to the left. There was also a very small patch of the same black deposit, shaded off on all sides, under the left anterior lobe; the intensity of this colour varied, but was greatest near the petrous portion of the right temporal bone: a very slight stain of the same dark carbonaceous colour was traced on some parts of the surface of the brain, corresponding to the darker parts of the dura mater. This grey appearance was evidently not in the substance of the dura mater, but almost confined to the arachnoid which lines it, and could in some parts be peeled off, leaving the membrane nearly natural. The surface of the dura mater, next to the bone, was of a natural colour and appearance,

“The heart was remarkably large, appearing to distend the pericardium; it was at least twice the natural size, and the parietes throughout very feeble and thin; but all the valves were healthy, and the heart contained no fibrin or coagulum, and very little blood. There was one small patch of disease near the arch of the aorta, but the large vessels were in general healthy, though they were much stained with blood.

“The other viscera appeared healthy, but had in some degree lost their usual characteristic colours by the changes of approaching decomposition; unfortunately the kidneys were not examined.”

The author conjectures that the heart was the primary source of disease, and that some spasmodic affection of that organ, connected with the gouty diathesis, had been the immediate cause of the sudden dissolution. The circumstances, he remarks, were not unlike those which occurred in the case of the late distinguished Dr. Marcet. *He*, too, had recently recovered from an irregular attack of gout; *his* death was instantaneous, and no obvious organic lesion, sufficient to account for the event, was found on post-mortem examination. In both, the body ran with great rapidity into decomposition. The peculiar appearance of the dura mater is certainly very interesting; it probably depended upon the injury which took place at the time of the paralytic attack, three years and a half before death, and had consisted originally in an effusion of blood upon the arachnoid at the part; and probably the pressure thus produced was the immediate cause of the extreme slowness of the pulse—a phenomenon which, in a less degree, is frequently witnessed in cerebral diseases attended with pressure.

MEDICAL GAZETTE.

Saturday, November 5, 1831.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”—CICERO.

PRECAUTIONS AGAINST CHOLERA.

WE entered upon the consideration of cholera now some months ago with a decided impression, derived from the

opinions of the Indian writers, that the disease was not contagious, and this sentiment has been indirectly hinted at in various preceding articles. No long time elapsed, however, ere we began to doubt the accuracy of this opinion, and latterly a farther acquaintance with the history of the disease, and a careful attention to its progress, and to the phenomena it has displayed in Europe, have led us to abandon our preconceived notions, and to yield our conviction in favour of contagion. The grounds on which this inference has been founded, we shall detail in another number; but as we have no object but to discover the truth, and as our feelings are not interested on either side, so we have given, and shall continue to give, all the information which reaches us, whether it make for or against the opinions at which we have at length arrived; and we earnestly call upon those who have adopted opposite views to follow our example in this respect,—an adjuration which the ex-parte statements of certain recent writers have called forth, though various circumstances lead us to fear that it will be unavailing;—the end in view with some, apparently being, not to discover which is right, but to maintain their own side, be it right or wrong.

If cholera be contagious, then there are obvious means of excluding it; we do not say that these will prove effectual, but that the nature, end, and operation of the precautionary measures, are apparent. If, on the other hand, it be not contagious, then there is no human contrivance by which its introduction can be prevented, or even impeded. Now, admitting that the mode of its propagation may be matter of reasonable doubt, we would ask, which is the more dangerous error—to hold that it is not contagious, and it turn out in the sequel that it is so, or to hold that it is contagious, and it prove to be other-

wise? There cannot be a shadow of doubt with regard to any thing so palpable. It cannot for a moment be denied, even by the staunchest anti-contagionist, that the direct tendency of teaching the public that a disease is not contagious, is to make them disregard those precautions which they would otherwise take against it; and thus, if the doctrine of non-contagion be erroneous, to multiply an hundred-fold the extent of the calamity. Let those, then, who ridicule the idea of contagion, beware, that the time do not come when the victims of their rashness shall denounce them as the deceivers that betrayed them into danger, and heap coals of fire upon their heads, by reminding the public of the exertions which they made to thwart the authorities in their reasonable endeavour to repel the invader, ere yet he had effected a landing on our shores.

To the quarantine now in operation we last week adverted, and we again recur, as affording the only hope which remains of excluding the disease from England; and if the regulations could be rendered as complete in practice as they are in theory, our hopes would be by no means faint; but with so extensive a coast to act upon, with so many temptations, and so many opportunities afforded by smuggling, of evading the sanitary precautions, we fear that much reliance is not to be placed on their efficiency. While, however, a chance of success remains, it behoves the press to co-operate with the government in carrying those measures into effect. True, they are injurious to trade, but what of that? the profits of the merchant must give place to the safety of the public: true, they are detrimental to the revenue; but surely it were better, if need be, to levy a tax upon the purses of liege subjects than upon their lives. Besides, the period of doubt cannot last long: if the disease come, why then

farewell to farther quarantine, at least by sea : if it be kept out, then the measureless benefit of its exclusion will reconcile the most prejudiced and discontented to the temporary inconvenience.

Regarding the progressive approach of cholera to the west of Europe as rendering it extremely probable that this country will be subjected to its visitation, we are gratified to find that the inhabitants are preparing themselves in earnest for its reception. Local Boards and Committees are everywhere being formed; the work of precaution is in progress, and a general purification has begun. That it is so, is to be attributed to the recent manifesto issued by the Board of Health, and circulated by the government in every town and village throughout the land. Oh, for the consistency of certain among our contemporaries, who doubtless, if their modesty permitted, could easily tell us in whose hands the care of the public safety might have been much better placed than where it is! First they raised a cry against the Board of Health, because they did too little, and in this perhaps there was some shew of justice; now the complaint is, that they have done too much. Their first directions were too general, their last are too particular; their first announcement was not sufficiently impressive to arrest attention, their last is calculated "to fright the isle from its propriety." True, the document circulated by the Privy Council is of a nature to excite alarm, but was it not high time that the people should be roused to a sense of their danger? Would it have been kinder and more benevolent to have let them sit with their hands before them till the enemy was upon them, rather than warn them to be prepared that they might repel the aggressor? Would these whining deprecators of the measures demanded by common prudence—would they have us, like the ostrich of the desert, run our heads into the bush,

and shut our eyes against the pursuer till we became his prey?

In such a case as this, and with a people wrapt up in the busy pursuits of life, an appeal to their fears was the only method by which they could be roused from their habitual indifference; and we rejoice to find that it has not been made in vain. The tone of mild precaution was disregarded; but the more vivid picture of approaching danger has arrested attention, and the whole coast is on the *qui vive*. It is true, that more of apprehension mixes in the exertions at present making than may possibly be warranted; but those who have paid any attention to the workings of the public mind, must have observed how soon it becomes habituated to existing circumstances, and resumes its composure under events which at first were viewed with dread. It is incomparably better that the people should look the evil in the face—the worst of the panic will be over before the disease actually comes, and its presence will not create an hundredth part of the consternation it would otherwise have done.

Entertaining these sentiments, we earnestly call upon our readers to co-operate, to the utmost of their power, with the local authorities in carrying into effect the recommendations published by order of the Privy Council*. It is very true that some of the suggestions for the isolation of the sick appear to us of doubtful expediency; but all the preliminary measures have our fullest concurrence, and the more completely they are carried into effect, the less hazard there is of the ulterior precautions ever being required. Every man may do something towards improving ventilation, enjoining cleanliness, and

* We have not deemed it necessary to insert the Regulations issued by the Privy Council for the prevention of Cholera, as they have already been so very extensively circulated.

urging the benefits of temperance. A desire to avoid susceptibility of the disease is one of the strongest motives by which to influence men's minds; already, indeed, has this salutary principle begun the work of reformation; and it is engendering habits of regularity, which the unaided precepts of prudence or morality have never succeeded in effecting. In France they have too much sense to keep the people in ignorance, lest they should be frightened; and it is ordered, that every house in Paris be visited by persons competent to judge of its condition as to ventilation, sewers, and other circumstances of a similar nature, so that not a family in that great metropolis but have the probable approach of the disease forced upon their attention; and we anticipate as the result, that all which human sagacity can devise will be put in operation to prepare for its reception. Why should it not be the same with us?—why are not the civil authorities enjoined to enforce the necessary precautions? Let us be prepared, if the disease should unhappily reach us, to meet the emergency with calm and well-directed efforts; and above all, let us not be betrayed into a false security by those who make light of a disease in which they have no experience. Those who talk the boldest while the enemy is not within sight, are generally the first to play the craven when he comes. Are they who exclaim that the alarm is false aware that it is ascertained that not fewer than an hundred thousand persons have been cut off in Hungary, and eighty thousand in Galatia, where the principles of non-contagion have prevailed, and where the people have waited for the disease in passive inactivity? Should the confident predictions with which the press has been teeming, that the disease will either not come, or come robbed of its terrors, prove fallacious, we should then have to encounter the

most fearful of all calamities in such a case—that of a sudden and general panic, by which the energies of the public mind would be paralyzed at the very moment when coolness and self-possession would be most required.

Since writing the above, our attention has been directed to some observations of Dr. James Johnson, recently published in the Times; we have also seen another letter from that gentleman in the Herald, into which it had been copied from the Courier; and we perceive that we are to be favoured, through the same medium, with a succession of papers of a similar nature. This somewhat singular mode of giving publicity to his opinions, the worthy doctor assures us, does not proceed either from “vanity or self-interest,” and that he has no end in view but “the good of his country.” That he should anticipate such a result from his epistles puts at rest the idea of “vanity” having any share in his motives. With regard to the absolute absence of “self-interest” we should not have been so well convinced had not the doctor given us the above satisfactory assurance; but for this, it is just possible, that having his name and address kept before the public in successive numbers of a daily paper in extensive circulation, and accompanied by the laudatory comments of a friendly editor, might have been regarded by ill-natured persons as having some slight weight in leading him to adopt a proceeding so unusual with respectable members of our profession. We subjoin an extract from the Courier, that our readers may judge of the tone in which the passages we allude to are written:—

“Dr. Johnson is, from his long acquaintance with the disease in India, and from his high standing here as a physician, a better authority, perhaps,

than any other in this country; and it is not very creditable to the Board of Health to have put forth their opinions publicly, without having consulted that gentleman.'

We cannot for a moment suppose that Dr. Johnson had any thing to do with the insertion of this, or other equally absurd paragraphs; but we do think that most men would have avoided affording them even the indirect countenance they receive from his immediately becoming a contributor to the paper in which they appeared.

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

ON THE IDENTITY OF SMALL-POX AND COW-POX, AND ON A MODE OF INTRODUCING THE VACCINE PUSTULE IN THE COW AT PLEASURE.

DR. SONDERLAND, of Bermen, the author of the paper which we shall here translate almost without abridgment, if his experiments be correct, has at length succeeded in establishing what physicians have long laboured to discover—a satisfactory and simple explanation of the protective power of cow-pox against small-pox; and has announced, we will venture to say, the most important discovery which has been made in the pathology of these diseases since vaccination was first introduced—by shewing that they are modifications of one another, and that cow-pox in the cow is simply small-pox in man, and may be produced in that animal at will by the variolous contagion. Of the authenticity of his facts we do not pretend to judge. All we can say is, that the author, if we judge from the language of Hufeland towards him, is a respectable practitioner, and a public medical officer.

"The simplest and surest mode," says he, "of producing cow-pox in the cow, and thus proving indisputably the identity between the contagion of cow-pox and that of human small-pox, is to follow the procedure here laid down.

"Take a woollen bedcover which has lain on the bed of a small-pox patient who has died during the suppurating stage, or is suffering from the disease in a considerable degree, and is lying in a small, imperfectly ventilated apartment; and when it is well penetrated by the contagion, roll it up immediately after death or on the fourteenth day of the disease, wrap it in a linen cloth, and then spread it for twenty-four hours on the back of a quey in such a manner that it cannot be thrown off by the animal. Then place it for twenty-four hours on the back of each of three other queys, and afterwards hang it in such a manner in their stall that its exhalations may rise upwards and be inhaled by them. In a few days the animals will fall sick and be seized with fever; and on the fourth or fifth day the udders and other parts covered with hard skin will present an eruption of pustules, which assume the well-known appearance of cow-pox and become filled with lymph. This lymph, which exactly resembles the lymph of genuine cow-pox, if used for inoculating the human subject, will induce the vaccine or protective poek. The only precaution which it is necessary to observe is that the person about to be inoculated shall not be exposed in any manner to the contagious effluvia of the cow-house either directly or through the intervention of the experimentalist's clothes, otherwise he may have natural small-pox.

"A bedcover impregnated with the variolous contagion, if firmly rolled up and wrapped in linen, and afterwards in paper, and then properly packed in a bucket, will retain the contagion for at least two years, so as to infect a cow with cow-pox, provided it be kept in a cool, shady place, where the temperature does not fall under 32 or above 52 degrees.

"My present occupations prevent me at this particular period from giving a full and scientific exposition of the consequences which must follow from this discovery; but I may state them shortly in the aphoristic form.

1. "This discovery is new; for, although many have suspected the identity of small-pox in man and cow-pox in the cow, and have in consequence performed inoculation with the matter of both, yet no one has previously ascer-

tained the possibility of transmitting the contagion to the cow in the gaseous form, so as to decide the question beyond all doubt.

2. "The desire of physicians and governments to discover cow-pox in cows, in order to revive the vaccine lymph, is more than fulfilled by the discovery of a simple method of engendering cow-pox in the cow at will.

3. "Jenner's discovery of the protective power of vaccination hitherto imperfect, is now perfected, because the hitherto unknown nature and origin of cow-pox are laid open.

4. "All previous uncertainty regarding the quality of vaccine matter, its degeneration, the loss of its protective property, and the like, must now cease, because we have obtained a clear insight into the nature of cow-pox and can lay down a substantial theory of its operation.

5. "This discovery must tend to widen the boundaries of physiology, pathology, and therapeutics, since it shews how the subtle contagion of small-pox, so hostile to the nervous system of man, may be conveyed in the aeriform state from him to the cow, excite in that animal a similar disease, but in doing so be changed by the special constitution of this class of animals into a permanent contagion of a different kind.

6. "An instructive lesson may be drawn from this discovery how the poison of diseases in the gaseous form may be communicated to the lower animals, and according to the difference in their constitution engender diversified products, which may be then used as protective means against the diseases from which they originated. Such, for example, may be subsequently proved of scarlet fever, measles, yellow fever, and plague.

7. "It is now clear why, in recent times, cow-pox has been seldom or never seen in the cow. For the cow-pox of the cow arises merely from infection by the variolous exhalations from men recently affected with small-pox, and coming in contact with the cow. As epidemics of small-pox have been rare during the last thirty years, cows could seldom be exposed to infection, and have therefore seldom exhibited the disease."—*Edin. Med. Journ. and Journal des Praktischen Heilkunde*, Januar. 1831.

BRONCHOTOMY IN THE HORSE.

The number of the Veterinarian for November contains four cases in which the trachea was opened, with the effect of saving the lives of the animals: these were all instances in which suffocation was impending from inflammation about the larynx. The following is the description of the operation as performed in the first case:—"An incision was made, about four inches in length, through the integument and sternothyroid muscle; a portion of one of the rings of the trachea was excised, large enough to admit one's finger; a thread was passed through the muscle and integument on each side, and fastened to the mane, to prevent the aperture from closing." The cases were treated by Mr. Toombs, of Great Barrington.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Oct. 29th.

The Cholera.

A REPORT having been circulated through the newspapers, that the all-engrossing subject of cholera was to be discussed here this evening, there was a very full attendance of members and visitors.

DR. SIGMOND in the Chair.

Whether the "order of the day" had been correctly reported or not, we cannot tell; but certain it is, that much time was lost in solemn silence after the president had announced that the business might now begin, until at length

DR. GRANVILLE volunteered to open the discussion. He expressed himself highly dissatisfied with the regulations of the Board of Health, which he thought were both useless and severe. On other occasions he had proved himself a stout advocate of contagion—as all would remember, on the Plague question; but he would now take credit to himself for maintaining as strenuously the opposite doctrine with regard to Cholera: on this question he was a steady non-contagionist. There was one great character of a contagious disease absent in cholera, there was *no eruption*. Nor was the spreading of the disease like that which would result from infection or contact: in St. Petersburg, for instance, where the utmost care had been taken to exclude the malady, *one* case was at length officially

announced, and in less than four days after there were between 400 and 500. How could this possibly have resulted from contagion, unless the sick had actually run out into the street, and touched and infected every one they met? The same conclusion was also to be deduced from the history of the disease, as it appeared in other places. He regretted that we had not sufficiently exact accounts of the pathology of cholera: of the matter or fluid discharged from the stomach, there was but little information: it was only occasionally, and almost by accident, he (Dr. G.) could gather that it was sour to the taste; from which he was naturally induced to infer the presence of muriatic acid, especially as the other symptoms would warrant the supposition, that the patients suffered as if poisoned with that acid. The learned Doctor having indulged, in the course of his speech, in a vein of merriment upon the published regulations of the Board of Health, and upon the history of the disease generally, as given by the contagionists, apologized, in conclusion, for having treated with levity a subject of such awful interest: he did it merely, he said, to give animation to his arguments.

Dr. O'SHAUGHNESSY contended that there was no ground for supposing that patients in cholera died as if poisoned with muriatic acid, or that there was evidence of any excess of that acid in the contents of their stomachs. And as to the absence of an eruption, he would instance hooping-cough, a decidedly contagious complaint, which was also unattended with an eruption. On the subject of cholera, Dr. O'S. expressed himself to be an advocate for its contagiousness: he instanced its making its appearance in the track of human intercourse at the greatest heights and lowest depths; and the recent information which had reached us with regard to the propagation of the disease among the pilgrims at Mecca, and thence spreading into Egypt, seemed to be decisive.

Dr. GRANVILLE, in explanation, maintained that pertussis was not contagious; and attributed the pestilential cholera among the pilgrims to their numbers, last season, and their long-continued prostrations over broiling sands, at 34° of Reaumur.

Dr. GREGORY thought that the contagious cholera was a *new disease*, sent by Providence to visit the earth, as the small pox was in the seventh century.

The cholera, too, would probably abide with us, like the small-pox, appearing from time to time, after its first ravages, in a virulent form. The cholera had originated in India in 1817, and it still continued to exist in that country, and most likely would never be eradicated. The same, no doubt, would be its destiny in Europe. With regard to quarantine, he feared no measures would be sufficiently rigorous to exclude the disease: nothing short of an impenetrable wall built all round the country could effect such an object.

Dr. JOHNSON called the attention of the Society to the difficulty of coming at exact information with regard to the mode in which the disease was propagated: the evidences to be found in books were suited to the writers' preconceived opinions. He took the latest book published on cholera—that by Mr. Kennedy—and what did he there find? The author professes to give a selection from the excellent Indian Reports, and, out of some hundreds, thirty-seven are given. Now it is a well-known fact, that the great majority of Indian practitioners are non-contagionists; yet, what has Mr. Kennedy done?—of his select thirty-seven, all but two are contagionists. As to cholera being a *nova pestis*, as Dr. Gregory would have us believe, he (Dr. J.) could not subscribe to any such doctrine. He had *seen* the disease himself, in India, twenty-seven years ago, and Mr. Curtis had had experience of it twenty years earlier. Nay, he was not sure but that Sydenham had witnessed it, in the peculiar cholera of 1669, as he says nothing about the presence of bile in the discharges of the stomach, in his account of it. Precautions for the exclusion of cholera are useless: even if the impenetrable wall of Dr. Gregory were built as high as the sky, the disease will come among us *if it chooses*.

Dr. STEWART made some remarks on the probable influence of certain vicissitudes which had taken place in the weather within the last year or two. Severe cold had been experienced in southern climates, and extreme mildness in the northern latitudes.

Dr. JOHNSON (after a pause in the debate) rose to express his opinion that the propagation of cholera can only be accounted for by the supposition of exhalations from the earth: there is something going on beneath the earth's surface that we know nothing about.

MR. KING sagaciously inquired, "whether any member of the Board of Health was present?"—and upon being answered in the negative, rejoined, in a solemn tone, "Then that is to be noted!" He then inquired, with equal solemnity, "Whether there was any evidence, or could any gentleman inform him whether there was any such thing as cholera at all in the world?"—(laughter.) He was then proceeding to panegyrisse Dr. Barry, and to propose that the discussion on cholera should not be resumed till that gentleman's return from Petersburg, when

MR. CHINNOCK moved an adjournment of the discussion to Saturday next (this evening); which was carried by general consent.

CLINICAL LECTURES,

Delivered in the Dispensary of the London University,

BY

DR. ANTHONY TODD THOMSON.

LECTURE III.

October 27, 1831.

Rheumatism—Remittent Fever—Epilepsy.

GENTLEMEN,—Since our last lecture one of the cases of Rheumatism, that of Pennifather, has been discharged cured, and two others are likely to be so in a few days. In all of these cases the severe symptoms yielded to the use of the Calomel, Opium, and Colchicum, and little remained but slight indications of pain, preceded by rigor in the evening, for which the Sulphate of Quinia was ordered, and speedily removed them. In the case to which I alluded in my last lecture—that of Cadwell, the swelling of the wrists, and the pain excited by touching them, had greatly increased; but I pointed out to you the cause of this, in the intemperate habits of the patient, who smelt strongly of gin, and who acknowledged that she had indulged in a few glasses of that cordial, to comfort the weak state of her nerves under her sufferings. I take this opportunity, gentlemen, of pointing out to you, that it is only in persons who indulge in the abuse of stimulants that I have ever seen any thing like the co-existence of Gout and Rheumatism, forming that mixed disease which has been named Rheumatic Gout; and, although I am aware that Rheumatism makes its attack on the most temperate and regular habits, yet I can assure you that it is infinitely more difficult to cure it when the use of wine or spirits is continued during the treatment of the disease, than when these

are altogether set aside. Indeed, I know scarcely any disease in which attention to diet and regimen is so essential as in Rheumatism.

The employment of Bark as a remedy in Rheumatism was in use as early as the time of Morton, who, although a bad authority in matters of theory, yet was an honest physician; and his word can be implicitly relied upon, in reference to the result of any mode of practice. His observations were afterwards confirmed by the experience of Sir Edward Huhn, Sir John Pringle, and Dr. Fothergill; but it was not until the clinical experiments instituted by Dr. Haygarth, on the effects of this remedy in acute Rheumatism, that its value was fairly appreciated. Dr. Haygarth's practice was, first to reduce the febrile violence of the attack by antimonials, and then to throw in the Bark. He found that in no case did any mischievous effects follow its employment; and when manifest relief was not obtained at first, it was generally afterwards ensured by suspending the use of the medicine, and again having recourse to antimonials, until sufficient evacuations were procured. In such cases, the Bark was not again employed until the inflammatory symptoms were abated. The perusal of Dr. Haygarth's work, and an entire confidence in his details, induced me to give his plan a fair trial; and, with little variation, I have continued to follow it ever since. I have, certainly, seen the Bark do harm in acute Rheumatism; but then the precautions necessary to be observed previous to its administration, have not been duly observed. The substitution of the Sulphate of Quinia for the Bark has only added to our power over acute Rheumatism: sometimes, I have found it to be requisite to combine aromatics with the Sulphate; in which case every indication has been answered by the essential oil of Calamus Aromaticus rubbed up with Sugar, as an Oleo Saccharum, and added to the Sulphate. I was induced to prefer this aromatic to any other, from having observed the powerful influence of the root of *Acorus Calamus* in curing Agues, when used in the form of infusion, as a vehicle for the administration of the Bark. In Sussex the powder of this *Acorus* is used alone as a remedy for the cure of Agues. When Bark has failed to fulfil the intentions of the prescriber, Arsenic has been occasionally employed, after the attacks of the rheumatic pains have become decidedly intermittent. My experience of its efficacy does not authorise me to speak confidently in its favour.

With respect to the use of topical remedies, you will soon perceive that I very rarely order them. I have several times seen recessions of the complaint follow the employment of Rubefacients; and as, in such cases, we have no method of preventing the disease from falling upon a vital organ, it is better either to reject them altogether, or to employ them with the

utmost circumspection. The only topical remedy which I have freely employed is the application of leeches to the pained part, followed by either emollient poultices, or the pediluvium, when the lower extremities are the seat of pain. The comfort of the patient is thus much improved; but topical bloodletting, however performed, does not contribute to the cure of the general disease.

From what I have already said respecting the bad effects of intemperance in retarding the cure of Rheumatism, it is scarcely necessary to force upon your attentions the propriety of prescribing a Milk Diet. Sydenham very properly interdicted the use of animal food and of all fermented liquors. Indeed, in every disease, if you reflect that remedies are intended to make a certain impression on the habit, you need not be informed, that the less this is interfered with, or interrupted by the administration of stimulant food, the more likely are the remedies to prove beneficial.

Before closing my remarks upon these cases of Rheumatism, you may expect that I should say something of Chronic Rheumatism, some cases of which are upon the books of this Dispensary; but, in my opinion, *Acute* and *Chronic* Rheumatism are the same disease, merely modified by duration; equally active as respects the symptoms; and, in fact, requiring the same plan of treatment. In private practice you will find this truth too frequently presenting itself to humble the vanity of the inexperienced practitioner: you will find patients labouring under Rheumatism after having suffered for ten or twelve months, who will inform you, that their pains are as severe as they were at the commencement of the attack; you will find the same hard, tense beat of the pulse; the same buffy coat on the blood; and the same pink deposit in the urine. Under these circumstances, however, the means that would have insured success, if employed in the early period of the disease, will not now succeed: and it is only under the administration of alterative doses of Calomel and Colonium, in direct combination with Sulphate of Quinia, or some other tonic, such, for instance, as the Buckbean, *Menyanthes trifoliata*, that we can contemplate a salutary issue.

In long protracted cases, when the pains are confined to particular joints, I have seen much benefit derived from a plan imitative of the Douch Baths at Aix-les-Bains. On reading an account of these baths, which are of a temperature from 116° to 142° Fah., I was induced to form an opinion that the principle of their action was percussion in conjunction with a high temperature. The Douching apartments, which are caves of the rock, have the hot water conducted into them through channels, that terminate in tin tubes of about two inches in diameter. A large stream of water falling from a consi-

derable height is thus directed upon the affected part, whilst the patient is immersed in an atmosphere of warm vapour. The sensation experienced resembles that of a severe cudgelling; but this is followed by decided relief, and the repetition of the Douching, at intervals of two or three days, generally produces a permanent cure. To imitate these baths, I set my patient in a chair, at the side of which is placed a bucket or large vessel capable of containing three or four gallons of boiling water, and envelop patient and all with a blanket, pinned close round his neck. In a few minutes he is bathed in a copious perspiration, and in this state he is directed to apply percussion to the pained joints by means of an elastic ball, made of cork covered with kid leather, and fixed on a handle of cane or whalebone, about a foot in length. I have seen the most decided benefit follow this practice; and one case, of seven years' standing, after the daily employment of this *dry douching*, if such an expression be allowable, my patient was beaten into excellent health, and threw aside a crutch, which he had for years been forced to use.

As a prophylactic, after an attack of Rheumatism has been allayed, you will find nothing so serviceable as the daily use of the Shower Bath. If the patient have been much reduced, and the re-action is likely to be feeble, the bath should not be taken until the system has been fortified with breakfast; but when the vigour of the habit is restored, it may be used immediately after rising in the morning.

Remittent Fever.

I have now to direct your attention, gentlemen, to the two cases of Remittent Fever which have lately been before you; the subject of one of them, Henry Schmidt, has been discharged cured; William Coates, that of the other, which is of a less decided character, has just been admitted. Schmidt is a German, 26 years of age, of a delicate frame of body, with black straight hair, hazel eyes, and a pale complexion. He is by trade a cabinet-maker. He informed you, that for some weeks past he has felt unwell, without being able to specify any complaint, except that his feelings differed from their usual state. About six days before his application to the Dispensary, he was attacked by a rigor, which was not followed by much increased heat of body, and by no sweating. It left him, however, extremely languid, and ever since he has been one day better and another worse; but on no one day has there been a complete intermission of symptoms. He has generally felt better in the morning; his uneasiness, accompanied with alternate heats and chills, gradually stealing on in the afternoon, and not declining until about midnight; but although these states

were of daily recurrence, yet they were evidently more severe every other day. On the day of his admission, 18th October, his complaints were, loss of appetite and all relish for food; he stated that he suffered from a constant, although slight nausea; the tongue was much coated and dry; the bowels were confined; the urine natural; and the pulse, which was weak and compressible, beat 100. He had constant severe headache; the skin was clammy, the extremities were rather cold, and he mentioned that he felt occasionally ready to sink, and could not command his ideas. He slept heavily, but awoke unrefreshed. He was ordered a pill containing gr. vj. of Calomel, to be followed by a brisk Cathartic, and a mixture composed of four grains of Tartar emetic, in eight fluid ounces of Camphor mixture; three table spoonfuls to be taken every fifth hour. The pill and draught produced two stools only; but the tongue was cleaner, and the reportsays, "this morning (October 20th) he has perspired freely, which has brought down his pulse to 88. The Antimonial has not produced sickness; on the contrary, he feels less nausea, and his headache is gone." The pill, purging dose, and mixture, were continued. On the 22d he felt much better in every respect, and his countenance had lost the anxious expression which so strikingly marked it at his admission. The bowels were still torpid; but the skin was natural, the tongue much cleaner, and the urine natural. He was now ordered a mixture, consisting of ʒj. of Sulphate of Magnesia, six fluid ounces of Infusion of Gentian, and one fluid drachm of diluted Sulphuric Acid, the fourth part of which was to be taken three times a day. Under the use of this mild aperient, a farinaceous diet, sub-acid drink, and rest, he continued improving until this day (the 27th) when he was discharged cured.

Although this case, gentlemen, may be regarded as a mild specimen of the usual Autumnal Remittent of this climate, yet it presents some points for remark; and merits your consideration as a form of disease which is likely to come frequently under your care. The first circumstance in the case to which I would particularly recal your attention, is the peculiar physiognomy of the patient, which on his admission was so characteristic of general suffering, and of disease affecting the nervous system. The countenance, which was pale, sallow, and pinched, wore a look of great anxiety; whilst the eye was indicative of a disturbed state of the mind. The contrast between this expression and the lively, open countenance which the patient now wears, presents a theme for reflection too striking to have escaped your observation, and affords me also an opportunity of pointing out to you the great aids which the attentive study of the physiognomy of diseases affords us, both in diagnosis and in forming a prognostic. The second remark respects the evidence which you may draw

from the symptoms of this case—the alternate heats and chills, the nausea, the muscular tremors and sinking, and the wavering state of mind—are evidence in support of the opinion that much of what constitutes fever is referrible to the state of the nervous system; in opposition to that theory which would refer all fevers to inflammation of one part or another of the body. In a fever, such as that now before us, there are no symptoms which would authorize us to fix upon one part of the body more than another as the seat of the disease. That the vascular system shares in the general derangement of the nervous, is obvious; and it is the conjoint affection of both which constitutes the disease.

On inquiry, I could trace this fever only to exposure to cold acting upon a weakened frame, predisposed to morbid impressions from depression of spirits, arising from want of employment and its necessary consequence—bad food, and a scanty supply of it. The poor man, who you know is a foreigner, had been for some weeks unemployed. There was a general state of languor prevailing; the functions were performed feebly, and torpor existing in some of the viscera, which, by throwing, as it were, the circulation off its balance, produced that irritable condition of the system which is so favourable to the production of fever. Thence vicissitudes in the weather, such as have lately occurred, succeeding to a warm summer, are likely to produce effects on the body which, in any other condition, it would resist.

With respect to the treatment pursued in this case, it was obvious that, with a compressible pulse at 100; with very little cerebral excitement, and without any symptom indicative of local inflammation, this case did not demand the abstraction of blood. The other case—that of William Coates—to which I have referred, presents evident symptoms of Pulmonary Inflammation, and, consequently, eighteen ounces of blood were taken from the arm with unequivocal advantage, and he bore the loss well. In Schmidt's case, the aspect of the countenance, the rigors and coldness of the extremities, indicating intestinal irritation, pointed out clearly the necessity of purging,—the only question was the kind of purgative to be employed; and, in ordering the administration of Tartar emetic, it was my object, not merely to evacuate the bowels, but also the stomach. I was fully aware that the severe pain of the head, which so closely resembled Meningitis that it would have authorized, in some minds, cupping or the application of leeches, depended solely on intestinal irritation; and, if the accuracy of the opinion may be judged of by the result, it was fully confirmed: besides, in evacuating freely the stomach and lower intestines, the habit, I hoped, would be prepared for the use of Sulphate of Quinia, should it be necessary in the decline of the disease. This, however, has not been re-

quisite, the action of the Calomel and purgative on the liver having emptied the hepatic ducts, and improved the biliary secretion, and that the Antimony having restored the suspended action of the capillaries. Nothing further was, therefore, required to accelerate the return of health than to keep up a moderately soluble state of bowels, and gently promote the tone of the digestive organs; an intention which has been fully accomplished by the means prescribed.

Epilepsy.

Before concluding this lecture, I will merely direct your attention to the case of *Epilepsy* admitted on Thursday, and defer any comments on it until we shall have time to estimate correctly the value of the treatment which is now in progress.

Arthur Leni, æt. 37, a green-grocer, of a sanguine complexion, complains of what he terms fainting fits, which attack him once or twice a day, and throw him down in the streets, whilst pursuing his occupation. On inquiring into the previous history of the case, it appears that he had a severe Epileptic fit at fourteen years of age, but it was not succeeded by another until seven years afterwards, when he suffered a second attack, and this was followed by fits recurring once or twice in every subsequent year, until two years since, at which time they increased in frequency, and now he is scarcely during any day free from a repetition of the attack. The fit, he says, comes upon him unawares, throws him down, and he becomes insensible; but he is informed that he struggles much, and he has lately bit his tongue: he continues in the fit for a quarter of an hour, after which it is followed by profound sleep. On awaking he can scarcely distinguish the objects around him, and this loss of vision continues for some hours. He complains of severe and constant headache; there is no intolerance of light during the day, but he experiences something like it in candlelight: the conjunctiva is slightly inflamed. There is *timuitus aurium*, like the constant ringing of bells; the tongue is furred; the pulse 92, small, and irritable; the bowels are open, and the urine is high-coloured.

He was ordered to be cupped behind the ears, and ℥viij. of blood only to be taken; eight grains of Calomel, and three of Extract of Henbane, were desired to be taken at bed-time, and followed by a brisk cathartic on the following morning. On the 29th, two days afterwards, he attended again at the Dispensary, and stated that he had had no fit since the cupping; but, although he admits that he is better, yet, he complains still greatly of his head, and of the *timuitus aurium*; and adds, that he feels also a sensation, as if there was wind in the head. He feels now and then faint; his appetite is still impaired, and the tongue furred; the

pulse is 84, and feeble; the urine is high-coloured. He has been ordered twelve pills, each containing one-fourth of a grain of Calomel, one grain and three-fourths of Camphor, and a grain and a half of Extract of Henbane: two to be taken every eighth hour: and in the intervals a purgative, containing 3j. of wine of the seeds of Colchicum.

The most singular incident in this history is the long period which elapsed between the first and the second attack; and the rapid progress which the disease has lately displayed without any obvious cause. This disease is one which may arise from visceral irritation, and in that event is curable; but whether the present case be of that kind can only be determined by attentively watching its progress.

NOTE FROM MR. S. COOPER TO MR. COULSON.

To the Editor of the London Medical Gazette.

SIR,

I WILL thank you to insert the following note to Mr. Coulson in your next number, if perfectly convenient to you—I am, sir,

Your obedient servant,

SAMUEL COOPER.

Dear Sir,—I beg to correct a mistake into which you have fallen, by stating in your lecture published in the *Medical Gazette*, that I had said nothing in my Dictionary, of the treatment of the patient previous to lithotomy. The account rather surprised me, and, at first, I imagined that the omission must really have been the fact; but, on referring to the two last editions, I observe that the subject has not been neglected, as may be seen by referring to page 803 of the 5th edition, and page 828 of the 6th or last.

With respect to the minute descriptions of the various modes of lithotomy, some of which are now obsolete, I regret that you do not appear to like them; but I and many other members of the profession feel an interest, and know that there is much utility, in the historical views of what has formerly been done in surgery. Were we always to pay due attention to them, we should not frequently suppose various schemes and practices to be quite new, merely because they are revived.

I remain, dear sir,

Yours very truly,

S. COOPER.

Great Russell-Street,

Oct. 29, 1831.

Wm. Coulson, Esq.

BOOK RECEIVED FOR REVIEW.

Elements of Anatomy, General, Special, and Comparative. From the *Encyclopædia Britannica*, Seventh Edition. By David Craigie, M.D. With Fourteen Plates.

LECTURES

ON

THE THEORY AND PRACTICE OF
MEDICINE ;

Delivered at the London University,

By DR. ELLIOTSON.

LECTURE VI.

Symptomatology (continued)—Indications afforded by the Pulse—by Examination of the different Regions of the Body—by the Excretions—Therapeutics.

I MENTIONED in the last lecture, gentlemen, that two parts of the body give us more information respecting, not their local affections, but the state of other parts, than those parts themselves, and that these were the face or the head altogether, and the hand.

I went over the chief symptoms which appear in the head, including the face, mouth, eyes, tongue—in fact, every thing above the neck ; and the chief symptoms which were indicated by the hand : and at the conclusion of the lecture I was speaking of the information obtained by the pulse, which is observed more easily in the hand than elsewhere ; not that the hand itself, or the wrist, has any peculiar quality of giving us information respecting the state of the circulation, although it is a great indication respecting other matters, but so it happens that the artery, (and it is a curious coincidence,) is to be felt better there than at any other part, and there we derive our chief information respecting the state of the circulation. The doctrine of the pulse is called *Sphygmica*.

I mentioned certain cautions which are necessary to be observed in noticing the pulse ; namely, to examine the pulse of each wrist, and in some cases to examine it also

at the heart. I mentioned likewise that it was necessary to take into consideration the age of the individual, the sex, the climate, the season ; and it is likewise necessary to ascertain the immediate circumstances in which the patient is placed—whether he is in a room of high temperature or not—whether he is near the fire or at a distance from it ; and also to ascertain what he has taken previously, because food accelerates the pulse, and the more stimulating its quality, of course the greater is the effect. You will observe different pulses at different hours of the day. It is necessary to take these matters into account, for if you were to find the pulse quicker than at your previous visit, and not to inquire whether the patient had taken food or not, or what other circumstance had occurred, you would be led into error. This is often a circumstance of great consequence ; for if you find the acceleration of the pulse accounted for by the patient having taken food, your prognosis remains as favourable as before. This has always been observed ; and you find in Celsus, what I dare say you all know, particular injunctions to medical practitioners not to feel the pulse immediately on going into the chamber of the sick, but to wait some time, to enter into conversation, and allow the flurry of the patient at the sight of his medical attendant to subside ; for it continually happens, that the pulse will augment from seeing the medical attendant, more especially for the first time. You will find the advice given by Celsus on this head to be in a high degree worthy of attention. It may appear trivial, but I do assure you it is of the utmost importance, and you will be led into a great error, especially in a public institution, if you were to put your hand on the patient's wrist at once ; it is better to ask some questions, and to remain some time before you feel the pulse.

However useful the information to be obtained from the pulse, if you neglect all these particulars, or if you take them into consideration and do not at the same time com-

pare the other symptoms with the state of the pulse, the pulse will lead you into very great error. The pulse itself, it is to be observed, affords only one symptom, and that may not be at all in unison with the real state of the patient. The pulse would sometimes lead you to suppose that there is the greatest danger, when there is none; and, on the other hand, it would sometimes lead you into security, when the patient is in the most imminent danger. However, this is not peculiar to the pulse; there is scarcely a symptom, which, if taken alone, would not lead you to draw a false conclusion. It is necessary, in examining any case, to take the whole collection of symptoms together—to set one against the other: sometimes you find them all harmonize, and at other times you find more or less confusion, but it is from the balance of the whole that you form your diagnosis and prognosis. The pulse has been called, in the most ancient times, *res fallacissima*, the most false of all symptoms; but the truth is, all symptoms are delusive, if taken separately: it is the collection which enables us to form our judgment.

I mentioned the chief varieties of pulses—the varieties which I think sufficient for all practical purposes, and which are the only ones that I have observed. You find in books an extreme *minutia* on this point, and I bink a great deal of absurd trifling. It is the Chinese, I understand, who have made the most minute observations on this subject: they describe all sorts of pulse, such as, I dare say, no one ever observed, and such as no one ever will.

Now as to these two parts of the body—the face, or rather the head altogether, and the hand—our observations upon them are chiefly made by sight and by touch; however, there is another sense that may be employed with respect to the head, and that is the sense of smell. The breath that proceeds from the mouth has sometimes peculiar odours, which, if we do not take pains to notice, we are compelled to observe.

The head and the hand, of course, give all the symptoms common to other parts of the body, when they themselves are affected. When either of these parts is inflamed, the various local symptoms present themselves. It is not, however, of local symptoms that I have been speaking, but symptoms indicating the state of the other parts of the system in general.

To proceed, however, downwards: the neck affords a certain degree of information, but not much. A long thin neck is frequently taken, in conjunction with other symptoms, as a sign of phthisis; whereas, a short thick neck indicates a disposition to fulness of the head and chest. The pulse in the neck is also an indication of different diseases. In many affections of the head, the carotids will throb violently, so as to be

seen at a distance; and, in many affections of the chest, the same circumstance is observed. Here, again, you see the necessity of attending to more symptoms than one. When you see a great throbbing of the carotids, you cannot tell whether it arises from an affection of the chest or of the head, for they both give rise to it. The pulsation of the jugulars is likewise frequently an indication of thoracic disease; a difficulty in the transmission of the blood through the chest will give rise to a great pulsation of the jugulars. I need not say that the tenderness of the neck indicates various diseases. By observing tenderness in that situation, you may frequently ascertain the existence of disease in the larynx, when otherwise you might be doubtful as to the nature of the affection.

With respect to the chest, it affords us a vast source of information; its sides and its shape indicate the general constitution. Phthical patients generally have a narrow and flat chest: the chest is contracted in various directions—shallow and flat in the front, and narrow at the sides. If a person be disposed to apoplexy, from mere plethora and congestion, and in gouty persons, the chest is disposed to be circular. Frequently the chest is deformed, and frequently it acquires an enlargement in various parts, from disease in the pleura. When a collection of water or pus, particularly of pus, takes place in the pleura, it is not uncommon to find the sides of the chest become enlarged. It is, therefore, frequently of great importance in thoracic diseases to strip the patient, and look at his chest: you may frequently discover by the eye a slight deviation in its two sides, which you cannot observe by the touch. A deviation so slight, that it would escape you if you merely resorted to measurement, is frequently perceptible to the eye. Of course, the touch will give you considerable information with respect to tenderness; and also with respect to the state of respiration, and the state of the heart, by the thrill which you experience. In some cases of difficulty of respiration, you find under respiration a thrill; and in certain obstructions of the heart itself, you find, on pressing over a part of the heart, a similar circumstance takes place, corresponding with the action of the heart. In some cases of aneurism of the aorta, and of diseases of the heart, you find by the hand a strong pulsation.

But although the sight and the touch give you this information, there is a third sense which imparts especial aid with respect to diseases of the chest, and that is hearing. The function of the lungs differs from the function of many other parts in this circumstance—it is performed with a noise, and so, likewise, is the function of the heart. The function of the brain and of the liver goes on without noise; but it is peculiar to the func-

tion of the lungs and of the heart that a certain sound should take place. If this noise take place in health, in sound physiology, you must expect that when the function of these parts is disturbed, the physiological sound will become pathological, that the sound will be altered; and such actually is the case. If this be the case, it is our duty to attend to it; if it be not the case, let those who say so prove that they are correct. We declare it is so, and we ask those who entertain a contrary opinion to listen for themselves.

As to the lungs, you will sometimes find the healthy sound of respiration cease altogether. A lung becomes impervious at a certain part, the air will not go through it, and this may arise from an obstruction to the course of the blood into the lung; but it may arise from the lung itself becoming consolidated, or from external pressure of the lung, the dropsical pleura preventing the lung from expanding. However, you may ascertain by this that respiration is not going on in that spot. Besides an absolute want of sound in certain diseases of the chest, you have in others an unnatural sound; the sound of respiration does not cease, but becomes strangely altered. You have information, also, not by listening only, but by striking. If you strike the chest, the nature of the functions of the lungs in health causes a hollow sound to be heard: the lungs are filled with air, and a hollow sound is necessarily produced. If something take the place of air—if the lungs become consolidated, or filled with fluid, or surrounded by it—it stands to reason that if you then strike that part of the lung, the air being absent, you will have a dull sound. This actually is the case, these things are physical necessities, they occur simply from the common law of physics; they must occur, and if they do occur we ought to observe them.

However, nothing would be more absurd than to attend to these auricular symptoms solely. The fault of those who merely employ the ear in diseases of the chest is just as great as the fault of those who do not employ it at all. There is a sufficient number of other symptoms frequently to point out the nature of the affection without employing the ear, but whether that is the case or not, it is as much our duty to attend to other symptoms as to those that we learn from the ear. You will, by looking at a patient while he is breathing, frequently find what is the state of respiration. You find that, like the pulse, it is more frequent than natural, or not so frequent as natural; we may have the *respiratio frequens* and *respiratio rara*, corresponding with the *pulsus frequens* and *pulsus rarus*. Now and then we find respiration performed suddenly, the inspiration and the expiration are sudden—and that is

called *celer*; and the opposite state, where the chest expands slowly, is called *respiratio tarda*, corresponding with the *pulsus celer* and *pulsus tardus*. These things may be learned simply by the sight. The respiration undergoes exactly such alterations as the pulse; it may be regular or irregular, it may be slow or quick, sudden or gradual. It may be deep or exceedingly shallow, little air being taken in at a time, and, on the other hand, you may have a full respiration. It may be full and deep, corresponding with a full and strong pulse. I do not mean to say that the function of the lungs and the pulse take place synchronously; but, as you have in the pulse quickness and slowness, fulness and smallness, jirking and sluggishness, so in respiration we have frequency and slowness, shallowness and depth, suddenness and sluggishness, irregularity, and so on.

When respiration takes place with difficulty, it is called, in medical language, *dyspnœa*: and if it be so difficult that the patient cannot breathe unless he sit upright, then it is called *orthopnœa*. *Orthopnœa* is merely an intense *dyspnœa*.

Independently, however, of the frequency of respiration or its slowness, you may hear particular sounds. You may hear a wheezing sound, which is called *sibilous*, or you may sometimes hear it performed with a snorting sound, which is called *sonorous*. Even without putting the ear to the chest, or employing a piece of wood as an intervening substance, it may sometimes be heard when standing at a little distance.

With respect to the *voice*, that affords you also much information. The voice is frequently suppressed, faint, harsh, and shrill; and these various changes will indicate great debility, or they will indicate particular diseases of the lungs themselves, or of the larynx, or of the air passages at large. From listening to the voice with the ear, in contact with the chest, or with the intervention of a piece of wood, or any similar substance, you will frequently ascertain that the voice does not sound as it sounds in general; so that you are able to say that an excavation exists in the lungs.

From a *cough*, too, with the naked ear we learn much, and the varieties generally enumerated are slight, severe, harsh, crowing, hooping, shrieking, tearing and hacking, loose and dry. There is an infinite variety with respect to coughs. Slight, severe, crowing, and hooping, I need say nothing about. You occasionally hear a cough tearing the patient to pieces, and it frequently indicates more disposition to spasm than actual inflammation. Now and then I have heard a cough which has been followed regularly by a shriek, so as to be absolutely alarming. At the end of every set of expirations, I lately heard one deep inspiration, not attended by a hoop,

as the whooping-cough, but by a shriek, as though the individual were about to have a dagger plunged into her.

In regard to the *heart*, you have great information by examining the chest itself; not only by the touch do you ascertain the force of the heart, but by listening you hear various alterations in its sound. Here again it is very necessary not to attend to any one symptom, or to the occurrence of any one sound, but to attend to the whole set of symptoms. Instead of the usual double sound which you hear in a healthy person, when the heart is affected in a certain way you hear a sound as if a pair of bellows were blowing, sometimes as if a file were in action, sometimes as if a substance were being rasped. If you attend to these only you may be led into error; but you frequently, at the same time, observe great difficulty of breathing on the slightest motion; you observe a swelling of the legs and a deficiency of urine, and you cannot but believe that there is organic disease. In other cases you only hear the sound, and then you would not be justified in saying there was organic disease, unless you listened time after time and always found the same occurrence. In observing these sounds of the heart, the greatest care is necessary not to form a judgment at your first visit. You may, by attending to the general symptoms, also see a sufficient proof of organic disease, but frequently there are no other circumstances present. These auricular sounds may arise from temporary causes, and you will not hear them two successive days. This shows that these symptoms, like those of the pulse, and almost every other, are never to be taken alone, but only in conjunction with other symptoms, and only when they have been dwelt upon carefully and repeatedly.

With respect to the *abdomen*—to descend still farther—the chief symptoms in that region are to be observed by the sight and the touch. The hearing gives you no great information respecting the abdomen, except in the circumstance of striking it, if it be enlarged. If you strike it, especially with the intervention of some little substance, either the finger or a piece of ivory, you learn whether the tumor arise from liquids or solids, by its emitting a dead sound as if you struck the thigh; whereas, if it arise from mere air, you find it sound hollow, like a drum. By going over the abdomen carefully, you may ascertain whether there is enlargement of any organ; and you may ascertain the shape of an enlarged liver with the greatest accuracy, the dullness occurring where you strike over the enlarged organ, and the hollow sound where the abdomen is in its natural state. This is the only point in which the ear is of much assistance. The ear is of the greatest use in diseases of the chest; but in the abdomen

you must more particularly have recourse to sight and touch.

Frequently, if you expose a patient in the case of abdominal disease, you may discover an alteration of figure which the hand cannot at once detect. Nothing can be more absurd than for a practitioner to prescribe at once for a patient who comes to his house for diseases of the chest and of the abdomen. It is very well to prescribe in that way for diseases of the skin, the head, and other affections; but with respect to diseases of the chest and the abdomen, if, in many cases, you do not listen, or have the patients more or less undressed, it is impossible to form a correct opinion. You may form a good guess, and you may be right; but you will not be able to form such an opinion as a philosophic mind would always wish.

In regard to the abdomen, by the sight you may discover enlargement, either local or general; but it is by the touch certainly that you acquire the greatest information altogether. You may feel an enlargement of various parts; you may feel the induration of different viscera; and, if there be fluid, you may ascertain its existence by the occurrence of fluctuation. But one great use of employing the hand to the abdomen is to ascertain the existence of inflammation; inflammations of the abdomen are detected easily in general—from the circumstance of the abdomen having no bony coats—by the hand pressing upon it; and it is always necessary, in acute diseases, carefully to examine the abdomen by means of the hand. In fever, and various affections of the alimentary canal particularly, if you do not carefully go over the abdomen with the hand, you may allow inflammation to escape you, which, if neglected, may prove dangerous. In fever, at any rate, it is right every day or two to feel the abdomen carefully, beginning at the epigastrium, which is the part most frequently affected, and going more or less all over it; but in every case where the abdomen is affected, you find it of the greatest importance to make these minute observations. It is nonsense to say that a physician is to use his pen and a surgeon his hand. Every physician must be more or less a surgeon, and every surgeon must be more or less a physician. It is as impossible for a physician to do without the use of his hand in the case of the abdomen, as it is for a surgeon in the case of fractures; and it is not creditable to any physician to pride himself upon not making these mechanical examinations, as I believe they are contemptuously called.

With respect to the *excretions* of the body, the sight and the smell give us the chief information. It is by the sight that we judge chiefly of the character both of the feces and the urine; the smell, however, gives certain

information in these particulars, as it also does with regard to the excretion of sweat. The sweat in many diseases is exceedingly sour, and in others it has peculiar smells, of which I shall hereafter speak. However, we sometimes are more minute in our observations respecting the urine; at any rate, it is necessary not to depend merely upon the sight and upon the smell, but to employ chemical means for ascertaining its quality. It is frequently requisite to ascertain whether the urine is acid, or neutral, or alkaline; it is right frequently to see whether it contains albumen or not; and in other cases it is necessary to ascertain whether it contains sugar. The most minute observations are sometimes necessary; and, of course, it is only with respect to the excretions that chemical minuteness is at all of service.

As to one sense, that of taste, I believe it can only be employed with regard to excretions, and I presume but with one of them—the urine. Some go so far in professional enthusiasm as to wish us to taste every thing; but it is not usual except in the case of the urine, and then, for the most part, it is better to get the patient to taste for himself. However, this is not *absolutely* necessary with regard to the urine, because by evaporation, and by weighing the urine, you can easily ascertain whether it contains sugar or not. I never yet in my life tasted it, but I have no objection, in diabetes, to taste the saccharine extract, for that is not urine.

Having gone through the chief of the organs of the body, I may say that the *whole surface* together gives such information as the head, but in a very inferior degree; we gain certain information, but it is undoubtedly far less than we gain from simply inspecting the face. From examining the whole body we learn whether there is a degree of fulness or emaciation; by observing its plumpness we can tell whether the patient is in condition or not. We observe likewise the dryness or the moisture of the skin, and the firmness of the flesh. We observe whether it is swollen or not by dropsy. It is to the surface of the body that we employ the sense of smell, in regard to the excretion of sweat. On the surface of the body we can ascertain the increased temperature of the patient; and for more minute observation a thermometer is employed. It is generally put into the *hand*, one of the two principal parts, or put under the tongue—a portion of the *head*. Every part of the surface of the body has its own affections; and it is there that not only the chief symptoms of cutaneous diseases—the symptoms of all its own affections, are to be found, but there often we observe affections of parts below. In inflammation, for example, of the *dura mater* from an injury, the surface immediately above frequently becomes *oedematous*. We

learn the state not only of the skin itself locally, but of parts beneath it, by looking at the skin immediately superjacent.

These are the chief observations which I have thought it necessary to make, generally speaking, on the third branch of general pathology, called *semiology*, or *symptomatology*.

The fourth division of general pathology is *therapeia*, or the general treatment and prevention of diseases.

Now in regard to most diseases nature has a tendency to get rid of them. It is ordained by providence, to a great extent, that the injurious causes to which we are exposed should have but a temporary effect, the body having the power of resistance, or they either existing temporarily, being applied but temporarily to the body, or being able to exert no more than a temporary influence. In this way it is that, generally speaking, we may say, although there are many exceptions, there is a tendency to shake off disease. This power of the body to shake off its morbid state is called by writers the *vis medicatrix nature*, or *autocrateia*. For example, if any thing too acid is taken into the mouth, a great flow of mucus and saliva is the consequence, which has a tendency to dilute the acid matter and wash it away. So with respect to acid matters taken into the stomach; the stomach has a tendency to reject them; or if they be passed through the stomach into the intestines, the intestines are excited to action, and they are got rid of. This is the general tendency of the frame.

Again, many causes of disease are only temporary. A person is exposed to a great cause of disease; the cause ceases, and, of course, in many instances the effect ceases likewise. It is not a necessary consequence, however, that the effect should cease because the cause is removed; but it very frequently thus happens. Again, there are other causes which cannot produce an influence upon the body, however long they are applied, for more than a certain period. If you take the poison of small pox, it produces a disease of only a certain duration; the patient may die, but if not, it can only last for a certain time; and when the disease has once occurred, the body, in the greater number of cases, becomes insusceptible of it again. These are the various means which nature has provided for getting rid of disease—for getting rid of noxious causes before they produce actual disease, and for getting rid of diseases themselves.

Some have so great a confidence in nature, that they leave every disease to itself, and that sort of treatment is called the *medicine of expectation*—*medicine expectante*. Such treatment does well in many cases; it is often the best in many cases, both medical and surgical, but it is totally inapplicable to a large number. No one with a violent in-

inflammation of the lungs would consent to sit down quietly in the hope that he would grow better day by day, when he knows that he may obtain immediate ease from the lancet, and get rid of the complaint. When a person has taken poison into his stomach, of course he would be mad to wait for nature to effect a cure; he would send for the physician's medicine, or for the surgeon's stomach-pump.

Now the treatment of the diseases of the human body is either preventive or curative; we either attempt to prevent disease from occurring, or we attempt to remove it; and when we cannot remove it we attempt to palliate it. The treatment of the human body in the way of preventing it becoming the subject of disease is called *prophylactic*; that which attempts to cure disease is called *curative*; and when we cannot attempt to cure a disease, still we may do a great deal in the way of palliation,—so that medicine is prophylactic, curative, and palliative. It is a great point very often to enable a person to live, while he must live, in comfort and happiness; and if he must die, it is a great point to enable him to die easily. In many cases we have to adopt both curative and palliative treatment together—that is to say, we aim at curing the disease, but we adopt palliative measures all the time, for the purpose of lessening any one symptom, or particular symptoms, which it is a desirable object to get rid of, or lessen, before the cure of the disease enables us to do so. For example, in the case of inflammation of the lungs, although we may attempt to cure the disease by bleeding, it is sometimes of the greatest importance to put an early stop to a violent cough by a narcotic.

In the treatment of diseases, whether it be prophylactic, (and it can hardly be called the treatment of disease when no disease exists; but we must allow an extended use of terms,) whether our means are to prevent diseases,—prophylactic, or whether they are to cure them,—curative; or whether they are to palliate them,—palliative; they may be of two kinds—they may be *rational* or they may be *empirical*. In the treatment of many diseases—not only in their prevention—we act rationally, we proceed upon general principles, and the whole treatment is in the highest degree philosophical. We make an accurate diagnosis, in the first instance; we then see what is the wrong state of the system, and we employ such means as are evidently calculated to remove that state. But in certain diseases, and in certain varieties of disease, we are obliged to act empirically—to act in a certain way without knowing why we are likely to be successful.

Now this empirical mode of practice is of two kinds—that is, sometimes we have a specific remedy for a disease without knowing why, and, in other cases, it is impossible to know the exact variety and cha-

acter of the disease, and we fire a shot at random that can do no harm, but which may do good. The treatment of inflammation is in the highest degree rational, the treatment of various spasms is the same, and the treatment of continued fever, too, I must think altogether rational. The treatment, however, of ague, of itch, and of syphilis, is empirical; for it is impossible to know why a few grains of sulphate of quinine cure ague, why a few grains of sulphur will cure the itch, and why syphilis will cease sooner if you exhibit mercury than if you do not. No one would *a priori* imagine that any of these remedies could have such a peculiar property; there is nothing in the nature of the disease, or in the nature of the remedy, that would lead us to any such conclusions. We also are obliged to be empirical frequently where we cannot ascertain the proximate cause of a disease. For instance, epilepsy arises, in cases innumerable, from an unknown cause situated in the head, or in distant parts. If we can ascertain that it arises from irritation, our treatment is rational, we remove this; if we can ascertain that it arises from an inflammatory state of the system, our treatment is rational, we remove this; but sometimes we cannot conceive that it arises from either of these sources, and then we use certain remedies that are known occasionally to do good; not that they are a specific against epilepsy, as bark is against ague, or sulphur against itch, but because they continually do good in the disease. They are not specifics, for they often will not cure one case out of many, and in many they are totally inapplicable, but still they frequently do cure the affection. I allude to copper, zinc, nitrate of silver, &c.

The mode of treatment which is pointed out from the circumstances of the case, is called the *indication*; and things which the nature of the case forbid us to do, are called *contra-indications*. To discover the indications which are necessary in the treatment of a disease, we must make a careful diagnosis of the nature of the case; then we must make an equally careful diagnosis as to the variety of the particular disease; and then we ascertain the stage of the affection, the exact strength of the patient, and the incidental circumstances—for example, we ascertain whether the place in which he lives at all accounts for his disease, or whether the season of the year is such as is likely to have affected him. We must likewise observe whether there is any peculiar constitution of the period. Sydenham used to mention the character of epidemics as the constitution of the year. Continued fever has sometimes been attended by so much tendency to debility, that evacuations were in the highest degree improper, and the patients did much better when they were allowed to take merely

simple food, with scarcely any other treatment. This has been the case during several months lately. If the patient were left alone, or treated with what in truth is no treatment at all, he has in most cases done well. If the least evacuation were attempted, the disposition of the disease was to great prostration of strength and rapid sinking. It is necessary, therefore, to know the constitution of the period; and, but for this, I certainly should have destroyed many patients by treating them as I had been accustomed to do; however, I was warned by the experience of others, and by careful observation of what was going on.

It is necessary also to know what are the contra-indications—whether there is any peculiarity in the patient. Some patients will not bear a remedy which is very appropriate to a disease; the disease may appear evidently to point out the necessity of a certain mode of treatment, but a peculiarity in the individual may render it exceedingly improper. This peculiarity sometimes relates not only to particular medicines, but to particular articles of food; and sometimes there may be some other disease present which forbids the employment of a remedy: for example, if a person have a hernia which cannot be well kept up, and you wish to give an emetic, you would try to do without it, lest you should force the intestines down too violently. You therefore see that you are not to be satisfied when you have given a name to a disease. It is a great point to make a good general diagnosis, but that will not do alone; you must make a more accurate diagnosis still; you must ascertain its minute variety, individual peculiarities, and all the other circumstances that I have just now mentioned.

In regard to the things indicated, they are divided generally into two classes—*regimen* and *pharmaceutical* means; the former consisting of injunctions in regard to the temperature of the place, to food, to exercise, and rest, and every thing of that description; and the latter respecting drugs. In prescribing medicines, it is necessary to recollect that, however excellent they may be, they are frequently rendered abortive by our want of attention to something else. There can be no doubt of the use of a large number of remedies, both drugs of the *Pharmacopœia*, and other remedial means; but I have seen them fail, not through any fault in themselves, but through something else that was not attended to when they were employed: for example, if mercury be given to arrest a violent acute inflammation, you cannot expect it to have that effect if you neglect to bleed the patient; and if, in addition to giving mercury, you do bleed him, you cannot expect to succeed unless you are particular with regard to diet. So, in diseases of the skin, there are many remedies which have a

particular operation which we cannot explain; they are not exactly specifics, but they do great good; yet the skin, in the midst of these diseases, may be in an inflammatory state, and if you do not bleed and enjoin low diet you cannot remove the affection. As no one symptom can be depended upon, so it is with remedies; and when you prescribe a remedy for a patient, you must take into consideration all the other points on which it is necessary to give directions.

Notwithstanding, however, the most scrupulous attention to all the circumstances I have just enumerated, you will often be disappointed in the cure of a disease; but you are not to be dismayed on that account. Our profession is capable of effecting the greatest good, chiefly in the way of preventing disease. By improvements with respect to cleanliness, with respect to air, with respect to food, and every thing else of that description, diseases are now scarcely known which formerly prevailed to a great extent; and we can do absolute good to a large amount in curing disease when it has occurred. A great many diseases are inflammatory; and over inflammation, by means of bleeding and other remedies, we have the greatest power. When we cannot eradicate a disease, still it is of great importance, and it is also a great blessing, to be able to mitigate pain; and it is to be remembered, that although we fail in the cure of many affections, yet, if we make the attempt, by degrees more knowledge will be attained, and those who follow us will be able to do what we cannot.

ON THE TREATMENT OF CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

SHOULD you deem the following hasty remarks worthy of insertion in your valuable publication, they are at your service.

E. STANLEY, M.D.

Brighton, Nov. 2, 1831.

In the treatment of cholera, it appears to me that sufficient stress has not been laid on the suppression of urine, and state of the urinary system, as shewn by dissections. If we consider the baneful effects caused by the constituents of urine being thrown back on the system, we shall, I think, be enabled in a great measure to account for some of the worst symptoms of the disease. Again, those remedies which at times have proved successful, such as

diluents, calomel with opium (a combination which, by preventing the former from running off by the bowels, may have operated on the urinary system,) hot baths and emetics, (by either of which a vicarious outlet by the skin was established,) &c. may have owed their efficacy to their directly or indirectly obviating that suppression. Besides, a return of the secretion and evacuation of urine being one of the most favourable prognostics, I should direct my immediate attention to a vigorous employment of diuretics:—oil of turpentine, in doses of 3j.—ij. repeated at short intervals, perhaps in combination with other essential oils, tinct. canthar. and other active medicines of that class; hot fomentations, blisters, or boiling water, to the perinæum; embrocations of oil of turpentine and cajeput, &c. to the spine, loins, and pubes, with a turpentine clyster, might, as far as practicable, be employed in conjunction with means calculated to cause a determination to the surface, (such as vapour or hot bath, &c.); and general bleeding, if not evidently counterindicated, or, as the immediate abstraction of blood from the *venæ portæ* system would seem desirable, leeches to the anus and right hypochondrium, or cupping to the latter. In some cases, especially where there is little or no vomiting, I should feel inclined to try the powerfully relaxant and revellent effects of tartarized antimony, in large doses, at shorter or longer intervals. From the colour of the blood, I am induced to believe the inhalation of oxygen would prove beneficial, and the depression of the vital powers might, perhaps, be relieved by the inhalation of nitrous oxide gas. As one of the remote causes of cholera may be a change in the electrical qualities of the atmosphere, electricity or galvanism, particularly the latter, might prove valuable auxiliaries. For the purposes of fumigation, the muriate of soda and sulphuric acid are, perhaps, the most convenient articles.

With respect to the question, whether cholera is contagious or not, I think it difficult in the extreme to come to a decisive conclusion; perhaps, it is idle to attempt it. The effluvia on which contagion seems to depend, probably vary in their quality and tendency to reproduce the disease, as much as symptoms do in number and degree; and again,

the susceptibility of those exposed to contagion, may be diminished or increased by numerous circumstances. Facts have almost indubitably shewn the disease, in many instances, to have been propagated by contagion; other more recent facts have proved that numbers have been exposed to it without becoming infected. This ought to convince the unbiassed, that the only conclusion we can arrive at is, that cholera may be either contagious or not, according to circumstances. Hence, while we ought not to neglect measures of precaution, we should at the same time use every means in our power to divest this fatal scourge of some of its terrors, and consequently to render individuals less susceptible of it, by dwelling on the fact, that many have escaped infection under very unfavourable circumstances, as well as on the probability, that if it should reach our shores at all, it may in this latitude appear in a milder form, both as to its contagious and other characters.

NON-MEDICAL TREATMENT OF CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

As all facts relating to the treatment of cholera are useful, whether derived from medical sources or otherwise, I send you the remedies resorted to by the Jews of Wiesnitz, who suffered less during the existence of the disease there, than other sects. My information is from a private letter to me, from one of the principal bankers and merchants of Frankfort S. M. and I give you the quotation *literatim*:—

“ One pint of strong Spirits of Wine;
 One pint of good White Wine Vinegar;
 One ounce of powdered Camphor;
 One ounce of flour of Mustard, or bruised Mustard Seeds;
 Half an ounce of ground Pepper;
 A full teaspoonful of bruised Garlic;
 Half an ounce of powdered Cantharides;
 Mix well in a closed bottle, and expose it to the sun, or some equal warmth, for 12 hours, frequently shaking it.

“ Let the patient be immediately put to bed, under warmed blankets (cover-

lids,) and let his hands and feet be rubbed powerfully and uninterruptedly with the above lotion, after it has been made warm. During this operation, let the patient take a glass of strong drink, composed of two parts of camomile flowers, and one part of balm of mint," (I suppose, of the infusion.) "Persevere in this course, and at the end of fifteen minutes, at the utmost, he will break out into a profuse perspiration,—the patient's head and body being kept well covered beneath the bed clothes. The patient must be kept in this state between two and three hours, and must not fall asleep. After this, remove the extra covering from the bed, and he will fall into a slumber, which may last from six to eight hours, and be accompanied by a gentle perspiration. When he awakes, he will feel weak, but the disease will have entirely left him, and he will require but rest and moderate diet to restore him.

"After rubbing, the patient must not have a single finger above the clothes,—the slightest chill would cause his death.

"When the cramps in the stomach come on, we apply very hot dry bandages of bran and ashes to the pit of the stomach, and, when necessary, a bladder of hot water to the region of the navel.

"The great point is, to produce strong perspiration, and to restore the circulation, which is drawn from the surface of the body, and thrown with frightful virulence on inward parts."

Note.—I have learnt, also, that these intelligent people used camphor extensively about their persons and apartments long before, and during the raging of the disease about them.

I send you this non-medical communication without comment; the medical reader will know how to appreciate it, and the general reader will derive advantage from its perusal.

I have, &c.

JOHN S. GASKOIN.

Clarges-Street, Nov. 5th, 1831.

REMARKS

ON

INJURY OF THE LENS.

By R. T. HUNT,

Assistant Surgeon to the Eye Institution, and Surgeon to the Lying-in Hospital, Manchester.

As the cases of injury of the lens, related by Mr. Mackenzie, comprise facts which are peculiarly illustrative of the advantages of extraction, in such injuries, I trust the following observations will not be considered entirely inapplicable.

The extraction of the lens when dislocated from its capsule, and lying in the anterior chamber, is a practice which has generally been advocated by those who have particularly attended to ophthalmic surgery, and indeed extraction of the cataract seems to have been first attempted in consequence of Petit's extracting an opaque lens, which had become so displaced as to occupy the anterior chamber. This plan of treatment appears, however, to have been confined to those cases in which dislocation of the lens and its consequences were the only injuries the eye laboured under. I am not aware that any writer had noticed the utility of early extraction in injuries of the eye, until the appearance of Mr. Barton's paper on that subject, in the *Medical Gazette* of March 20th, 1830. Since that period, a considerable number of complicated injuries of this organ have been thus treated at the Manchester Eye Institution, and the general result is such as will at least entitle this method to further consideration. It may be right to mention, that nine of these cases were published in the 4th No. of the *North of England Medical and Surgical Journal*, in a "Report of the advantages of extracting the Lens in such injuries."

When a considerable period has elapsed after the accident, previously to the examination of the patient, there is much difficulty in determining which of the diseased changes in other parts have been produced by injury simultaneous with that of the lens, and which are to be considered as consequences of the lens' displacement. For instance, a blow on the eye dislocates the lens

without immediately affecting the retina; this latter structure, however, gradually suffers, in consequence of the lens remaining dislodged, and amaurosis is the result. In another case, the blow which dislocates the lens causes concussion of the retina, and instant amaurosis. Suppose they are examined six weeks afterwards, when the injured eyes of both patients have become amaurotic; how can an observer then distinguish one case from the other? But let the lens be extracted, in such an instance as the former, as early after the accident as is possible; this will certainly prevent that injury of the retina which the displacement of the lens from its natural situation is stated as having produced. I have stated that amaurosis may occur, not only as an accompaniment of dislocated lens, but also as a consequence of such an injury. This is rendered more than probable by the frequent super-vening of this disease upon the operation for depression, in which the lens is dislodged with much less injury to other structures than when its displacement is caused by a blow. After the operation, patients frequently possess good vision for a time, which subsequently deteriorates, the case terminating in amaurosis. When, therefore, greater violence causes the dislocation of the lens, it is not assuming too much to state, that there will be at least an equal risk of the retina becoming affected. The lens was extracted in three of Mr. Mackenzie's cases; but although its removal appears, in every instance, to have relieved the pain and irritation which had previously existed, yet very little improvement of vision resulted, owing probably to the length of time which had elapsed before this practice was resorted to; for as the lens produced such severe symptoms, after the eye had been so long accustomed to its new position, it is evidently reasonable to conclude, that an equal, if not greater, degree of irritation must have existed soon after the occurrence of the injury. The author recommends extraction, not only in cases of dislocation of the lens, where other parts are uninjured except by its displacement, but also where other structures (the cornea, for instance) are implicated in the injury; but this recommendation is not clearly stated; it is merely implied in the treatment adopted, particularly in Case III., and in the observation, that "The lens

was extracted by Mr. Rainy with the same striking relief which extraction generally affords in such cases." Upon carefully examining Mr. Mackenzie's *Practical Treatise on the Diseases of the Eye*, in which no such observation occurs, I conclude that the practice has been adopted since his publication of that useful work; and it would be a great addition to the evidence, of the advantages of extraction in such instances, already before the profession, if one, who has long possessed and still retains such ample opportunities for the observation of diseases and injuries of the eye, would make public his favourable report of such treatment.

Whilst writing the foregoing observations, a very unusual case of dislocation of the lens came under my notice, viz. that which Mr. Mackenzie calls the sixth variety of this injury.

Thomas Siddal, a weaver, ætat. 66, received a severe blow on the eye on October 18th, which caused much swelling of the eyelids, &c. After this had subsided, he found his vision injured, and applied at the Institution on the 24th. There is a semi-transparent tumor at the upper part of the eyeball, of a roundish form, about the size of a large bean, apparently produced by some body lying between the conjunctiva and globe, immediately behind the ciliary ligament. The cornea is perfectly free from injury; the iris detached from the ciliary ligament on the temporal side, and drawn upwards towards the swelling already noticed, so as to distort the pupil, which is rendered still more irregular by effused blood adhering to the lacerated iris. There is a slight degree of intolerance of light, and considerable vascularity of the sclerótica and conjunctiva; but the pain is much less severe than might be expected from the extent of injury. There is no constitutional irritation.

Considering the tumor as formed by the dislocated lens, I passed a cornea knife through the distended conjunctiva, when the lens was easily removed entire; it was perfectly transparent, and of the yellow colour usually found in advanced age. Its removal was not attended by any escape of either vitreous or aqueous humour, and the lids were kept closed by court plaster, in the usual manner.

Oct. 28th.—The progress of the case, up to the present time, is very favoura-

ble. He can now distinguish objects, and there is no appearance of opacity in the pupil; but when the extent of injury and the age of the individual are considered, it would not be judicious to expect that even the present degree of vision will remain. I shall reserve a more accurate report of the case until I am enabled to state the condition of the eye when a considerable period has elapsed since the occurrence of the accident.

OBSERVATIONS

ON THE

DEAF AND DUMB.

BY JOHN HARRISON CURTIS, Esq.

THE condition of the deaf and dumb has of late become a subject of more than usual interest. An opinion having long prevailed that such afflictions are of rare occurrence, the public sympathy has been powerfully excited by the correct statement promulgated respecting the comparatively large proportion of individuals labouring under partial or total privation of hearing, and of speech, in the united kingdom. For the reception and maintenance of sufferers, so strongly entitled to the compassionate aid of the benevolent, many institutions have been founded, but they have all proved inadequate to prepare the deaf and dumb for general intercourse with society. Another disadvantage attending them is, the regulation by which no applicant is admitted before the age of nine years, for it not unfrequently happens* that four, five, and even seven children in one family are so afflicted as to possess equal claims on these specific charities.

Having been led to consider the great number of sufferers, in comparison with the establishments provided for their reception, I ventured to propose a plan, which was first suggested by me in 1817, to the Governors of the London Deaf and Dumb Asylum. On that occasion I recommended, as a measure of primary importance, a minute examination of all children born deaf and dumb, with the proviso, that for every child

presented for admission, there should be produced the report of a surgeon upon its case, as being curable or otherwise, and I advised that none but incurable cases should be admitted. Under this regulation, it appeared to me that the worst cases would be most certain of reception; and that in all curable cases an opportunity would be given for trying such methods as might appear best calculated to afford relief, if not effect a perfect cure.

From the abstract of a report made by M. Husson to the Royal Academy of Medicine in Paris, on the method adopted by M. Itard for the cure of the deaf and dumb, it appears that M. Itard has presented to the minister of the interior *three memorials*; the first relating to the various methods hitherto employed for the cure of congenital deafness, including those pursued by the author himself during a long course of practice; the second, containing a detail of experimental treatment adopted in nearly two hundred cases, with the view of determining the advantages and disadvantages of injections through the eustachian tube into the internal ear, an expedient apparently recommended to public confidence in a recent report of the institution; and the third, adducing arguments against the last-mentioned process, and proposing one which M. Itard considers as exclusively entitled to preference, being a medico-physiological method, calculated in his estimation to afford relief in very many cases of congenital deafness. To the last of these alone the present address refers, for according to M. Itard, absolute deafness is extremely rare; he admits not more than one-fifth of the cases that occur to come under that definition. Every endeavour, then, should be made, to relieve any curable defect or obstruction, before a case is abandoned as hopeless. It should be recollected, that to restore to society one who suffers from accidental causes, and to render him useful by the scientific development of his natural powers, is much more satisfactory and laudable than to lead him through the indirect and exclusive forms of an artificial and symbolical education, however expedient this may be with regard to desperate cases, for which all practicable resources have been tried, and have proved unavailing. In offering these observations, as confirmed by daily practice and experience, I have no hesi-

* Vide Report of the London Deaf and Dumb Asylum.

tation in declaring, that the more I see of these afflicting cases, the more I am convinced that much relief may be administered, and that not one should be relinquished as desperate until all means have been tried to remove the defect. In very young children I have found the most frequent causes of deafness to arise from obstructions of the eustachian tube—from various affections of the membrane of the tympanum—from viscid mucus impacted in the bottom of the meatus, and, not unfrequently, from those herpetic eruptions which often afflict infants during dentition. Notwithstanding the general advancement of medicine and surgery, and the improved methods of cure for various diseases, it is to be regretted that those of the ear, though not numerous, are attended with more inconvenience than any others; and hence, until of late years, little attention has been paid to their relief, or, at least, little skill or ingenuity has been employed in multiplying and varying the expedients likely to attain that object. In considering the chief obstacles that present themselves, it is to be observed in the first place, that the structure of the ear is extremely complicated, the parts that compose it are principally internal, and the diseases that assail it chiefly concealed from view: hence, in very many cases, arise the uncertainty of diagnosis, and the difficulty of adopting a proper course of practice. In the second place is to be noticed the extraordinary prejudice which, ascribing all congenital deafness to malformation of the organ of hearing, denounces the disease as incurable, and depreciates all attempts at relief as at once nugatory and fallacious, or, at least, painfully uncertain. A third objection, which has been often urged, is the difficulty of applying remedies immediately to the parts affected. Yet means of relief may be employed without inconvenience, and often with success. Congenital deafness, and that which is observable soon after birth, frequently depends upon casual circumstances. In the ear, as in every other organ of the body, cases of defective formation may present themselves; and in these, deafness is incurable. But the obstruction of the eustachian tube, the most frequent cause of this disease in young children, is generally removed without difficulty. At the Royal Dispensary for Diseases of the Ear, as well

as in my private practice, I have had opportunities, which have not occurred to any other practitioner in the metropolis, of examining different applicants, for, perhaps it is not generally known, that the governors, in order to afford more prompt and extensive relief, have often, with the most benevolent views, ordered that all deaf and dumb patients should be admitted without recommendation; I have thus been enabled to try every mode of treatment, and none has appeared to me so efficacious, after having had the ears well syringed, (an operation rarely performed on deaf and dumb children,) as blisters and gentle emetics. The following I have generally found most successful:—

R. Antimonii Tartarizati, gr. ij.

Pulv. Ipecac. gr. xxiv.

Aquæ Distillat. ℥vj. M. fiat mistura.

In order to suit the medicine to the patient, a dessert spoonful is given every five minutes, until it operates.

To illustrate these observations, the following cases are given:—

Mary Haines, aged four years, was admitted as a patient at the Royal Dispensary. She has been deaf and dumb from her birth. She was the only one of her family afflicted with these defects, though her parents had five children besides herself. She was much emaciated, and in such a state of general debility, that I had considerable doubts whether she would survive. On examining the ears, I found a great deficiency in the ceruminous secretion. Her general health being so deranged, the first indication was to endeavour to invigorate the constitution, and this, by proper means, was happily accomplished. The usual remedies, such as blisters, injections, and other topical applications, were then employed, with the occasional use of purgatives. By the prompt and judicious adoption of these means, I am happy to state, she has acquired the inestimable faculties of speech and hearing.

Mary Anne Hagne, on recovering from a severe fever which had endangered her life, became deaf and dumb. She was brought to me when she was seven years of age; her case seemed of the most hopeless kind, and nothing but the strong importunities of her mother could have induced me to make attempts for her relief, and persevere in the treatment. After a number of ineffectual

fectual essays, and various modifications of my plan of proceeding, I had the satisfaction to restore her to hearing and speech. This case strongly exemplifies the advantages of perseverance in the treatment of these complaints, and demonstrates the necessity of repeated and prolonged trials of the various remedies, even in the most discouraging circumstances, especially when it is considered, that the faculties which we seek to restore, are of primary importance, and will qualify the patients to become incalculably more useful to themselves and to society. In regard to this child, I may also remark, that her speech was very probably improved in consequence of her being at a common school, for we are well aware how forcibly the principle of imitation acts upon children, and what great efforts they will make to perform whatever they see done by others.

Selina Hewitt was admitted a patient at the Royal Dispensary for Diseases of the Ear, afflicted with congenital deafness and dumbness. It was with some hesitation, in regard to success, that I undertook her case; but after commencing a plan of treatment similar to that adopted in the former instances, I soon observed indications of gradual amendment, and she has made such progress as to be able to hear and speak, much to her own satisfaction and to the heartfelt gratification of her friends, who awaited the result with great solicitude.

Thomas Mayo, aged two years and a half, had become deaf and dumb from accidental causes. When he was about a year old, the servant who had charge of him, having taken him out for an airing, imprudently detained him in the park too long on a very cold day, the consequences of which exposure were febrile symptoms, accompanied with sore throat. On examination, I found the eustachian tube obstructed, probably from inflammation when labouring under the sore throat; there was also a discharge from the meatus. I employed the emetic mixture, which was repeated several times, at intervals of a week. This completely removed the obstruction; the discharge was cured by means of injections, and a slight alterative course of medicine. The child is now able both to hear and speak.

James Lawlor, a boy about five years old, was sent to the Dispensary, from Ireland. His mother, who accompa-

nied him, informed me that he was born deaf and dumb. He was also blind of one eye. Finding, on examination, an obstruction in the eustachian tube, I ordered the emetic. When I saw him, three days afterwards, his mother informed me that he could distinguish loud sounds. The emetic was consequently repeated, with even greater apparent success than before; and as he continues under my care, I anticipate the most favourable results. I adduce this case as a proof that slight affections, if early attended to, may be treated by this curative process with the fairest prospect of ultimately effecting the total or partial removal of the malady. It is requisite to repeat the emetics frequently, in order to remove the collections of mucus which lodge in, and obstruct, the tubes. The period required for the success of such means, must vary in different cases, according to the degree of obstruction. No remedy is so suitable for the purpose of removing these obstructions as emetics; of this every well-informed practitioner must be convinced, when he considers the nature of their action. The operation of emetics is not, as is imagined by the vulgar, confined to the evacuating the contents of the stomach; these remedies produce great increase of the secretions of the mouth and throat, as well as of the juices of the stomach; by their action the biliary and pancreatic ducts are emulged, the secretions of the liver and pancreas are augmented, as well as those of the glands in the vicinity of the mouth and throat; stagnant fluids are put in motion; morbid congestions and accumulations in various parts of the system are removed; the excretion of mucus from the lungs is promoted; the general absorption of the system is increased; the circulation is rendered freer; the blood is diffused more equally over the system, and topical determinations are, in many instances, lessened or removed; the articular and pulmonary exhalations are very sensibly promoted; an action is also excited in the nervous system, which is often highly salutary in nervous disorders. The excitement produced rouses the sensibility of every part, without producing debility; and thus the different minute parts of the organ are enabled to recover their energy, and structural mischief that may be forming is prevented.

Soho-Square, October 20, 1831.

BOTANY OF NEW ZEALAND;

BEING A

Description of Trees, Plants, &c. indigenous to that country.

By GEORGE BENNETT, Esq. M.R.C.S. &c.

[With Engravings.]

Edwardsia Myerophylla, SALISBURY.
Sophora tetraptera . . . FORSTER.
Kowhy, or *Kongia*, of the natives of NEW ZEALAND.

Natural Family, *Leguminosæ*.

Class, *Decandria*. Order, *Monogynia*.

THIS tree is the *Kowhy*, or *Kongia*, of the natives, and attains the height of from forty to fifty feet, but it rarely attains more than five feet in circumference; it is of very irregular growth, and is seldom seen straight; it is found in good soil. The wood is hard and durable, and is used principally by the natives in the manufacture of their paddles, and instruments for digging, &c. The flowering season is in September, and the two or three subsequent months.

There are two species at New Zealand, both of which have been correctly figured in several botanical works.

CRYPTOGAMIA.

Asplenium lucidum . . . FORSTER.
Uru-urn-fenua of the natives of NEW ZEALAND.

It is difficult to assign a reason why certain trees and plants are held sacred by Pagan worshippers, as the mistletoe (*Viscum album*) among the Druids; the Tamanu (*Calophyllum inophyllum*) and Aito or Toa (*Casuarina equisetifolia*) among the Tahitians; the *Ficus religiosa*, and others among the Hindus; and the Fern now under observation among the New Zealanders. To queries on this subject, an answer is usually received of "its being the custom," probably originating in some lost tradition, or else some superstitious legend is found attached to them.

This species of *Asplenium* is a sacred plant among the New Zealanders, and is called by them *Uru-urn-fenua*; it is used by the *Tohunga*, or Priest, when

praying over a sick person; he waves (during the time he is endeavouring to avert the anger of the gods by his prayers) a frond of this fern; if it breaks it is a sinister omen, and the sick person will not be expected to recover.

When the *Tohunga* consults the spirits previous to engaging in war, he also waves a frond of this fern in his hand during the time he offers his prayers; if it breaks it is considered that the spirits are adverse to their engaging in war, and the enterprize is consequently given up.

It is also used by the natives as a badge of mourning. When a wife mourns for her husband, she sits wailing in her hut, with a frond of this fern, bound as a fillet around her head: a husband does the same when he loses his wife. They are careful not to burn, or use this plant in cooking their food.

When a Chief has his hair cut, the *Tohunga*, or Priest, is present. After the operation is performed, the Chief holds a frond of this fern in his hand, during which the Priest prays over him, frequently taking the frond and shaking it; after which it is dipped into water, and shaken over the Chief; if it breaks it is regarded as a sign that the life of the Chief will be but of short duration; and if one of the leaflets only is broken off, it is expected that one of the family will soon die; if the frond remains entire, it is an indication of success and long life.

The fronds are usually two feet in length.

Ephialis Sp.

Puredi, or *Kauwéré*, of the natives of NEW ZEALAND.

This is an unpublished species of *Ephialis*, and is figured in Parkinson's Botanical Drawings, made during Cook's first voyage, among the collection of Sir J. Banks now deposited in the British Museum. It is the *Puredi*, or *Kauwéré*, of the natives of New Zealand; seldom attains more than the height of forty feet, but in circumference is usually from ten to twelve feet. The wood is very hard, and is seldom used, as it injures the axes on attempting to cut it. The wood is of a yellowish colour, and yields a yellow colouring sap on being cut, and when washed. It is not used by the

natives, however, as a dye, or for any other purpose. The flowers are elegant, drooping, and of a pink colour. The fruit is a drupe, the seed inclosed in which has on it numerous irregular projections; the fruit is of a

bright red colour. The following drawing was made from a recent specimen at New Zealand. The fruit is delineated of the natural size. (a) The four stamina attached to the calyx; (b) the pistil.

Daerydium cupressinum, BANKS and SOLANDER.

Remu, of the natives of NEW ZEALAND.

Natural Family, *Coniferae*.

Class, *Diacia*. Order, *Monadelphina*.

This species of *Daerydium* is named *Remu* by the natives of New Zealand; it attains the height of eighty to ninety feet, but seldom exceeds fifteen feet in circumference. The timber is hard, of excellent quality either in plank or spar, and is considered the hardest timber of all the New Zealand pines. This species is not found so abundant as the other pines, growing only in particular districts. The wood in colour is an intermixture of white and red; no gum-resin exudes from it. The fruit is eaten by the natives, and was described by them as a small red berry, containing a black seed. This species of *Daerydium* is the one mentioned by Captain Cook as the spruce fir of New Zealand.

It is figured in Parkinson's Drawings, made during Cook's First Voyage, in Sir Joseph Banks's collection, now deposited in the British Museum, from which the engraving in Cook's First Voyage seems to have been made.

Phyllocladus Species.

Tánakáá Táwai, or *Toatoa*, of the natives of NEW ZEALAND.

Natural Family, *Coniferae*.

Class, *Diacia*. Order, *Monadelphina*.

This tree, the *Tánakáá Táwai*, or *Toatoa*, of the natives of New Zealand, is an unpublished species of *Phyllocladus*; it attains the height of sixty to seventy feet, but seldom exceeds fourteen or fifteen feet in circumference. The timber is heavy and hard, of good quality either in plank or spar, and of a white colour, but not equal in durability to the Kowri, and its weight renders it less valuable for spars. It sinks in water; a gum-resin exudes from it, but in very small quantity.

The bark of this tree is used by the natives of New Zealand for dyeing a red or black colour*; the mode of pre-

paration is as follows. The bark is pounded, and then placed into a vessel of cold water, into which hot stones are placed until the water boils*. After the bark has been boiled for some hours, the liquid becomes of a dark red colour: it is then left to cool, the decoction strained, and is ready for use. The Flax (*Muka*) to be dyed is then placed into this liquid; and after remaining for some time, when taken out, is found of a red colour; it is then placed into the sun to dry. This red colour is not indelible, but will stand frequent washings before it comes out. When the flax is to be dyed a black colour, after having undergone the before-mentioned process, it is placed in mud, (usually from marshes, &c.) and remains in it for the space of twelve hours, after which it is taken out, dried, and is found of a shining black colour†. The bark of this tree is generally used in the recent state, but its virtues also remain when dried. The beautiful black colour of the flax used in the manufacture of some kinds of the New Zealand mats, is procured by the above-mentioned process. The bark of this tree is sometimes stripped off by the natives, the outer part removed, and the inner bark, which is of a dark red colour, is worn round the waist as an ornament, but is not of any durability.

Podocarpus Species.

Mai, or *Matai*, of the Natives of NEW ZEALAND.

Natural Family, *Coniferae*.

Class, *Diacia*. Order, *Monadelphina*.

This tree, the *Mai* or *Matai* of the natives of New Zealand, is an unpublished species of *Podocarpus*. It attains the height of from eighty to ninety feet, and from ten to twelve feet in circumference; it is scarce in the vicinity of the sea, but is found abundant inland. The wood is of excellent quality, of a red colour, resembling cedar. One tree was cut down at Wyshaki Cove,

* This is the native mode of heating water, as they have no vessels which can be placed on the fire.

† I know not, on analyzation, of what chemical properties (but probably salts of iron are held in solution) the marsh mud may be found composed, but it will be an interesting subject for further investigation. In Ireland it is customary among the poorer people to steep the undyed woollen cloths in the water of the turf-bogs, which dyes the cloth of a dark colour.

* I believe that a black dye is wanted in this country, which, on exposure to sea air, will not lose its colour; if so it is to be found in the black procured from the bark of this tree, as the New Zealand mats dyed with it do not fade even when washed in salt water, but it rather gives a greater brilliancy to the black.

River Thames, from which I procured specimens; it measured thirty feet in height, and six feet in circumference. The torins, or New Zealand flutes, (which are tastefully carved,) are made from this wood; they are not hollowed out, but formed of two portions, which are accurately joined, tightly bound with cord made from the New Zealand flax, and the joined portion well luted.

London, Nov. 4th, 1831.

MEDICAL GAZETTE.

Saturday, November 12, 1831.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”—CICERO.

MODE IN WHICH CHOLERA IS PROPAGATED.

THE only rational source of confidence and tranquillity under the existence of an approaching danger, is a thorough acquaintance with its nature, and a timely adoption of the measures requisite to avert its actual presence, or if this cannot be, at least to limit its extent, and controul its influence. On this ground it is that we think the public ought to be put in possession of all the most correct and useful information which can be obtained on the subject of Cholera. Now the two most important points to determine are, first, the manner in which the disease spreads, that we may know how to avoid it; and, secondly, the best mode of treating it, should our previous efforts at prevention fail.

The first of these—or the manner in which cholera propagates itself—is a consideration of vital importance to the interests of the community; and it is one with regard to which a large portion of the press has done, and is continuing to do, mischief which may prove irreparable: we allude to the efforts which are made to convince the public that the disease is not contagious. The

motive of the writers we doubt not to be good, but they err lamentably in judgment, because the evidence against their views is of the most convincing description to an unprejudiced mind, and because the direct tendency of their doctrines is to lead those who adopt them into unnecessary danger. Let it not be supposed that we are among the “terrorists,” or that we concur in the sentiments of the panic-stricken writer in the *Quarterly*, whose recommendations, if adopted, would sever every bond which links society—would cause the parent to abandon his child, and the child his parent—converting the land into a scene of distrust and desolation worse, infinitely worse, than has resulted from the disease itself even where its ravages have been the greatest. But, because others may have magnified the evil, is that any reason why we should shut our eyes, and refuse to look upon it as it really is? If small-pox were raging epidemically, should we not tell the public that the surest way to escape was to avoid the source of contagion?—precisely on the same principle, then, we urge the imperative necessity of their being made aware that cholera is propagated, and, consequently, may be avoided in a similar manner; and we pledge ourselves to prove in the sequel how small the individual risk is if proper precautions be taken, and how great the peril if they be neglected.

The first point, then, to determine is, whether it be contagious or not; and here we would premise that many of those who argue this point are wholly incompetent to give an opinion upon it at all*. But instead of interrupting our narrative by arguing with them here, we proceed to grapple with those who are of the medical profession, and who, better acquainted with such subjects, still prefer the fanciful and incon-

* See what we have said further on this subject at p. 214.

gruous explanations, which their ingenuity enables them to offer, of the phenomena regarding cholera, rather than adopt the plain straight-forward path to which undeniable facts and common sense alike conspire to lead them.

First, then, we hold that the great majority of intelligent persons, who have had opportunities of witnessing the disease, or of examining on a large scale the evidence afforded by others, are of opinion that it is propagated by contagion. This has not only been denied, but the very reverse has been asserted by the anti-contagionists to be the case; and as it is a question, not of reasoning, but of recorded facts, we shall proceed to prove that we are right in our assumption by quoting the opinions of the best authorities, as stated in various public documents.

The disease, it is known to all, whether it had previously existed or not, first attracted notice, and excited alarm, in 1817, when it broke out in the Delta of the Ganges, and thence gradually over-spread the whole of India. Now it has been said that the Anglo-Indian practitioners almost universally regarded the disease as non-contagious; and it is true that the majority, though by no means all of the regimental surgeons in India, came individually to this conclusion. It was deemed expedient, however, to appoint at each presidency a Board of the more experienced and intelligent medical officers, to examine and collate all the returns transmitted to head-quarters, and to sift the whole body of evidence upon the subject. The result was, that at Madras and Bombay the disease was unequivocally admitted to be contagious. At Calcutta, on the other hand, no report was ever drawn up by the Board collectively, but merely by one member of it, Mr. Jamieson, who gave his own individual opinion against contagion. While, however, he did this in one part of his paper, he expressed himself in another in such a

manner as to shew, either that his opinion was not perfectly made up, or that he actually admitted the doctrine of infection as existing when emanating from a considerable number of persons. The following quotations will shew that we represent this matter correctly:—

Bombay Report.—“It appears, then, incontrovertible that this disease is capable of being transported from one place to another, as in cases of ordinary contagion or infection, and also to possess the power of propagating itself by the same means that acknowledged contagions do.”

Madras Report.—After citing numerous illustrations of the infectious nature of the disease, and alluding to the objections of the anti-contagionists, it is added—“Diseases avowedly infectious, such as small-pox, measles, &c. have not at all times the power of spreading epidemically; for while it is certain that their exciting causes are never wholly extinct, it is only at particular periods that these diseases become epidemic. The same may be the case with cholera. . . . The sudden appearance and disappearance of cholera, however, unlike the progress of known infectious diseases, is not admitted as being irreconcilable with the doctrine of infection, especially if the disease be of sudden invasion, after the application of the exciting cause.”

Bengal Report.—“This much, however, may be affirmed, from a review of the whole progress of the epidemic in this quarter, that the infectious medium, in whatever it consisted, was limited within a very circumscribed circle, and was very slowly extended. If, setting aside the circumstances militating against it, we take it for granted that the infection was truly received by the centre and Hansi divisions, from the detachments above-mentioned, we must believe that the disorder, although not communicable by contact from person to person, was so from one large body to another large body; and that, when the poison got head amongst a number of men, it assumed some new quality, so as, when mixed with the atmosphere, to become infectious. What constituted this additional quality, we cannot pretend to tell.”

When the disease at length made its appearance on the south-eastern fron-

tier of Russia, medical commissioners were appointed at Orenburg, and other places, with whom its mode of propagation was a primary object of investigation, and the result was, that "the local boards, as well as the physicians, have been fully convinced that the cholera does, in fact, disseminate itself from one man to another, and by this means travels from place to place*." Still holding on its course, the cholera ere long reached Moscow, and here a considerable number of medical men adopted the anti-contagion side of the question; in consequence of which a special commission was appointed by the Emperor, and the evidence adduced before them led them to report, that they did not think the disease was transmissible *by goods*; but they said not a word at variance with the opinion previously given by the supreme Board at St. Petersburg, that "it has resulted from observation that the contagiousness really exists," and that the contagiousness of cholera is "in some instances incontestible†;" and we learn that "at a consultation of forty of the most respectable physicians of this city [St. Petersburg], thirty-eight came to the conclusion, after mature deliberation on the documents laid before them, that the disease was infectious, and only two were of an opposite opinion‡."

To Moscow also repaired Dr. Albers, a Prussian physician, who stated to his government that the disease was contagious: the same view of the subject was taken by Dr. Walker, an English physician, resident at St. Petersburg, who had been sent to Moscow;—and MM. Moreau de Jonnés and Gravier transmitted to France a similar opinion.

When the disease manifested a tendency still to spread, other European governments, alarmed at its progress, em-

ployed commissioners to examine its phenomena, and to ascertain, if possible, its mode of propagation. Austria, Sweden, and Holland, sent intelligent persons to the spot where it was raging, and all with one voice have pronounced in favour of contagion. From England, Dr. Russel and Dr. Barry were dispatched; and if the opinion of the latter, who was previously known to be a contagionist with regard to other disputed diseases, may be received with some suspicion, no one can reasonably call in question his zeal in investigating, or his fidelity in recording facts. But even if his evidence were rejected altogether, no similar objection can be brought against that of Dr. Russel. Indeed his opinion, on the very principle which might invalidate the other, becomes of greater weight when we state that he had imbibed the doctrine of non-contagion in India, but that what he witnessed in Russia has removed his preconceived notions, and that he advocates this doctrine no longer*. At Warsaw it is said that the disease was regarded as not being contagious. By whom was it so regarded? By an English surgeon (Mr. Searle), who had already committed himself on the subject, having recorded his opinion in a work published some time before he went; and by a few Quixotic young physicians from Paris, who were so ignorant of the laws of contagion as to regard inoculating themselves with the blood, or tasting

* Official documents published at St. Petersburg.

† Official Report, published at St. Petersburg.

‡ Private letter from Dr. Russel.

* At the very moment we are writing we have received wet from the press the second edition of Mr. Orton's work, decidedly the best which has yet appeared upon the subject of Cholera. Like Dr. Russel he had rejected the doctrine of contagion, but can no longer resist the evidence in its favour. The following passage is highly creditable to his candour:—"It was not without astonishment that many of the profession in India heard that the Medical Board of Bombay, in 1818, held the disease to be contagious. My feeble voice, in common with the great majority, was raised in opposition to the—as it appeared—monstrous dogma; but the march of time and events, the great accumulation of facts and gradual removal of prejudices, have wrought in my mind the same revolution they have in many others: the opinion of the contagious nature of the disease has been gradually gaining ground even in India, and seems to be the general one in Europe—*Magna est veritas et prevalet*."—Orton on Cholera, 2d edition, page 514.

the evacuations of patients labouring under cholera, as an *experimentum crucis*; when it is notorious that no inference whatever can be drawn in favour of their views from these disgusting proceedings. Of these gentlemen we may remark that six out of about twice that number who went to the Polish capital, have perished*. Certain it is that both Diebitsch and Skrznecki, the commanders of the Russian and Polish armies, were satisfied that the pestilence was contagious: and the government at Warsaw, guided by the opinions of their most intelligent men, adopted the same view, as will appear by the following extract from one of their proclamations:—

“Ever since the battle of Iguinie we have had to struggle against that contagion, which attacked us not only in the camp, but even in our capital We were already congratulating ourselves upon having deprived our enemies of one means of injuring us, and upon having rendered a fresh service to Europe, but on the 26th of May the battle of Ostrolenka brought the two armies into contact, and the cholera once more made its appearance, as well among our soldiers as among the inhabitants of Warsaw†.”

So also with regard to Berlin, from whence we have the following account by Dr. Becker—himself, alas! subsequently a victim of the malady:—

“It may finally be stated, that the manner in which the cholera has appeared and spread in Berlin, perfectly warrants the conclusion, that this disease is always produced by a peculiar human effluvium, which in its mode of generation and diffusion shews some analogy with that of the *common typhus fever of Great Britain*, but extends its deleterious effects to a limited number of persons only, who are rendered eminently susceptible by cold, intemperance, fatigue, fear and anxiety, diarrhoea, and other previous diseases‡.”

* Viz. MM. Hugon, Collé, Michaud, Barrie, Grezes de Saintour, and Le Gallois. We are unable to say whether they all died of the cholera or not.

† Circular of the Polish Government respecting the cholera morbus.

‡ Private Letter from Dr. Becker.

And lastly, with regard to this part of the question, hear what an intelligent writer says, from a totally different quarter:—

“*Valeni del Mount*.—Having observed in the public prints an opinion put forth by some physicians that the cholera morbus, even when epidemic, is not contagious, I think it right to state, that, in this country at least, it is undoubtedly communicated in the same manner as plague or scarlet fever—by contact or approximation. Thus the thirteen cases of that malady that have hitherto occurred in this place, have been all of them distinctly traced to the above source*.”

But it will probably be asked, are there no places in which the local Boards regard the disease as non-contagious? There are. Opinions to this effect have been expressed at Riga and Dantzic; but we are inclined to place little reliance upon them; first, because no sufficient grounds of this exception to the more general sentiment are stated; and, secondly, because the extent to which both these places are dependent on their trade, renders some degree of distrust almost unavoidable as to the impartiality of their decision; just in the same manner as we have seen the existence of cholera at Sunderland denied, in letters from that place, published in the daily papers. Another non-contagionist presents himself at Dantzic, in the person of Dr. Hammet, who was sent there by the English Government. With regard to the communications of this gentleman, we can only say, that we think the Board of Health would have acted more judiciously if they had published them. We presume that they have been prevented from doing so by their extreme prolixity; still the illustration which they afford of the loose manner of reasoning adopted by the non-contagionists, would indirectly have strengthened the opposite side of the question, while

* Official letter from Mr. Blatte, the English consul, to Lord Cowley.

their suppression may lead those who have not seen them to imagine that they have been withheld on account of evidence against contagion—which, in fact, they do *not* contain.

We have thus shewn, then, the utter groundlessness of the common assertion, that they alone think cholera contagious who have not seen it, and that, on the contrary, the immense majority—not of illiterate persons, but of those capable of forming a judgment on the subject—have espoused the side we advocate. Nor is it a trifling addition to the probability of this view being correct, that it has been unanimously adopted by the Board appointed in London, numbering as it does among its members some of the most eminent of our civil practitioners, as well as those at the head of the medical departments of the army and navy.

But in coming to the conclusion at which we have arrived, that cholera is a contagious disease, we have not been influenced by these authorities farther than as an inducement to examine with attention, at the same time with candour, the evidence which had led so many to an inference, which, we are free to confess, was at variance with our views with regard to certain other diseases, which by many are regarded as contagious; and the following are the circumstances which have decided our opinion:—

There are three modes in which disease may pervade a district—it may be endemic, epidemic, or contagious. Now if we apply the characters of the two former to cholera, they will not be found sufficient to explain its phenomena; or rather, they will appear manifestly to be inconsistent with them.

The extent to which cholera has spread, and the diversity of the localities which it has occupied, at once set at rest the idea of its being what is usually understood by endemic; and there remains only that we should choose between the

two latter. Diseases which are epidemic, without being contagious, break out in distant places either simultaneously, or travel with a rapidity, and in a manner, that defies all calculation; cholera travels slowly and progressively. Epidemics march on the winds, and cannot be arrested; the progress of cholera has repeatedly been stopped. Epidemics generally prevail in tracts of country analogous as regards humidity, temperature, soil, elevation, or some other obvious similitude; cholera has exerted its dominion alike in the marshy jungles of Hindostan and the arid plains of Persia—the burning sands of Arabia, and the snow-bound provinces of Moscow. Epidemics, unaided by contagion, prevail for a time and disappear; cholera, like small-pox, scarlatina, and other undeniably contagious maladies, has never wholly left any country it once has visited; it still lingers in Bengal, where it commenced, and, in fact, wherever it has laid its envenomed hand, though it may occasionally relax its grasp, it still retains its hold. These considerations render it, *prima facie*, improbable that cholera should be merely epidemic. Let us now see what evidence of a direct kind there is of its being contagious.

Before doing this, however, we must request our readers to keep in mind, that the evidence of any disease being contagious is derived from a consideration of many facts, with regard to the circumstances attending its extension from person to person, or from place to place; and that, though perfectly demonstrative to men of ordinary reasoning powers, and whose minds are unprejudiced, it never is of that overwhelming and intuitive nature which forces conviction by a direct impression upon the senses. So much otherwise, that Sydenham, who witnessed the ravages of small-pox on a great scale, seems to have entertained no suspicion

that it was contagious; yet no reasonable man of the present day doubts that it is so. But though this be the mode of its propagation, and though it be thus *communicable*, it does not follow that it will in every instance be thus *communicated*. It is a remarkable fact, with regard to all the animal poisons, that some peculiar state of the individual is required in order to bring him under the influence of the disease: thus it is recorded by Dr. I. Hunter, that 21 persons were bitten by a rabid dog, and only one became hydrophobic. Does any one suppose that, because eleven escaped the effects of the poison, therefore the twelfth, who took the disease, did so from some other cause, and not from the bite? Yet this is precisely the argument of the non-contagionist with regard to cholera: the numberless cases in which the disease has directly followed exposure to some one having it are set aside, and some other explanation is offered as to the origin of the disease, because, in certain other cases, persons have been exposed to the same cause with impunity. How, then, is it with regard to complaints which universal opinion has now acknowledged to be *transmissible*—are they always necessarily *transmitted*? Take measles: probably there are none of our readers, who have had but a moderate share of experience, who have not met with this kind of case: measles breaks out in a family—it affects A, B, and C, successively, and, proving mild, the parents are anxious that all the children should have it; and, accordingly, a fourth child, D, is exposed to it by being allowed to eat, play, and even to sleep with the others; yet D refuses to take it, and passes the ordeal unaffected. Does any one thence suppose that measles is not infectious? On the contrary, we merely say that D was not at that time susceptible of the disease, and we know that, on another occasion, this same child may become affected with

measles, from a degree of exposure not nearly so great as that which had previously been resisted. So also, with regard to small-pox, an immense proportion of mankind are incapable, from the protecting influence of vaccination, of having this disease communicated to them; but does any one thence doubt as to the mode of its transmission to those who do receive it? Our object is to impress upon the minds of those interested in this question, that the fact of a disease being transmissible by infection, and so communicated to those who have it, by no means implies that it must of necessity be transmitted to all who are exposed to it. There is no instance of any disease, however infectious, in which this is the case; and therefore the argument against the transmissibility of cholera from man to man, founded on the notorious fact that many men are constantly exposed to it with impunity, is a complete *non sequitur*—absolutely illogical; and which, if admitted, would prove, by parity of reasoning, that neither small-pox, nor scarlatina, nor measles, nor any other disease, was either infectious or contagious. The kind of evidence, therefore, by which any disease can be shewn to be infectious, is not that every, or nearly every one exposed to it becomes affected, but that, on the one hand, its appearance in individuals, or in places, so frequently follows approximation to those who have it—or on the other hand, the exemption from its attacks, while it rages around, is so frequently preceded by a careful avoidance of the presence of those affected, as to render it impossible for us to give any rational explanation of the phenomena, without looking upon exposure to the presence and the subsequent occurrence of the disease, or the exclusion of its presence and the continued exemption from the disease, as standing in the relation of cause and effect.

Now, keeping in mind that the infec-

tious nature of a disease is to be deduced chiefly from the multiplication of probabilities, rather than from proofs approaching to mathematical demonstration, the first point to which we would direct attention is the mode in which cholera travels. We have already said, that epidemics overrun whole countries, either travelling with the wind, or at least with equal rapidity; but cholera journeys more leisurely. It proceeds from place to place successively; and, being at any given spot, it never jumps over any great intervening space to another similar locality, but, be the adjacent district moist or dry, high or low, healthy or unhealthy, if only there be men in it, and these have any intercourse with their fellows where it then is, the disease is sure to visit them. On the great scale it moves along the principal roads and navigable rivers, first affecting the towns and villages by the wayside, and subsequently extending to those more remotely situated. "Change of air and climate has apparently no influence on the progress of cholera*." "When once established in a marching regiment, it continues its course in spite of change of position, food, and other circumstances†." In short, it travels as man travels, stops where he stops, and proceeds again at the time, and in the direction, in which he resumes his journey. Moving along with the caravans of the east, it was approaching the city of Teheran, in Persia, when the Shah resolved to shut his gates against it. The travellers were obliged to make a circuit, in order to avoid the place; and thus did this sagacious Persian protect his domain from the visitation of this scourge for no less a period than eight years, though it raged on all sides around him; an example which shews what might have been accomplished had any precautions been

taken in India to arrest its progress; but unfortunately none whatever were adopted. The instance of Teheran is, we believe, the first in which the quarantine was fairly tried;—it was commenced in 1821, and it was not till 1829, owing to some remissness, probably engendered by this long exemption, that the disease at length gained admission. The Russians, too, arrested it on its first irruption at Astrachan, but allowed it to spread on its reappearance in 1830; and, indeed, after this no effectual attempt seems to have been made to stop it on the eastern border of Russia. Not only were travellers allowed to proceed, but "they who could flee the city fled, and as the malady was not considered contagious, servants, labourers, Tartars and Russians, were permitted to rush into the country*." From this time it branched off in various directions, according to the routes of the different fugitives; and there are some circumstances connected with its course which strikingly illustrate its disregard of every thing except the path followed by men. From Astrachan it proceeded up the Volga, but without touching the Don, till a cossack, who had been sent from the station named Katchalinskara on this river, to buy provisions at Doubooka on the Volga, died of the cholera on the 7th of August, after his return home. From that time the malady spread successively through the different Cossack villages along the Don†, and arrived at Azof in October. We request our readers to attend to this circumstance. The cholera travelled up the Volga a certain distance—was carried across to the Don, where it was till then unknown; and while on the former river it continued its course upwards, running nearly north-west; on the latter it

* Professor Lichenstein.
† Madras Report.

* Letter from a clergyman at Saratov. Quarterly Review, November.
† Crichton, &c.

held its way down (having first joined this river near its source), running in a direction nearly south-east. Thus during the month of September 1830, cholera was marching on two nearly parallel lines, but in opposite directions—on the one from south to north, and on the other from north to south—an occurrence easy of explanation, if we admit that it was carried by the persons travelling in these directions, but totally inexplicable on any other principle.

Again, in every instance where cholera invades a new country, it does so on a frontier next some district already infected; or, if it attack an island, it does so at some sea-port. Thus in Ceylon it first broke out at Jaffnapatam and Columbo, in Sumatra at Acheen, in Java at Batavia, in the Isle of France at Port Louis, in Bourbon at Port St. Denis, in *Britain at Sunderland*; and, in fact, the rule is universal; nor can any rational explanation be offered of the circumstance except that of the disease being imported. Persons on shore, in the neighbourhood of vessels having the disease, never take it unless some intercourse has taken place with the crew; and the converse holds equally true, that vessels arriving off an infected place remain free till they have had some communication with the shore. The illustrations of both these facts are too numerous to admit of any doubt. By sea then, or by land, we still find cholera accompanying man; and is not this a strong presumptive proof that it is carried by man?

But are there no exemptions from its so general influence—have no favoured places escaped its visitation? Yes, there are such exemptions—there are such places; and their history proves that there is one method, and only one, by which it may be turned from our doors. Exclude men, and you exclude this pestilence. To one example of this (that of Teheran) we

have already alluded; but the point is too important to be left without farther proof. Let any unprejudiced man read those which follow, and we think he will see in them powerful evidence in favour of our argument:—

“Many gardens and farms in the neighbourhood of Astrachan remained exempt from the epidemic, having broken off all intercourse with the diseased districts. In many villages, too, where similar measures of security were taken, the issue was equally fortunate, although the cholera raged all around them; for example, in the lordships of Smirnov, Beketov, and Prince Dolgoruki, in Sarepta, eight miles from Zaritzin, and some other places*.”

“The Moravian colony on the right bank of the Wolga, and several German colonies in the government of Saratov, around which the disease was violent, adopted the system of exclusion, and were also unhurt. At Caramala-Gubeewa some Russian peasants, living together, scarcely a hundred yards from the village, shut up their hamlet on the first report of the disease having appeared in their vicinity, and by enforcing a strict quarantine during the prevalence of the epidemic, remained in health†.”

“Mr. de Lesseps, the Consul of France at Aleppo, when the cholera approached that city in 1822, retired, in company with all who wished to be of his party, to a garden at some distance from the city. His asylum was inclosed with walls, and was surrounded by a large fossé; there were only two doors, one for entrance, the other for going out. As long as the malady lasted, he admitted nothing from out of doors without submitting it to the precautions observed in lazarettoes. His colony comprised *two hundred* persons, and consisted not only of Franks more or less acclimatised, but also of several natives. *Not a single individual contracted the disease*; while, at the very same time, within the city, four thousand beings perished in the space of eighteen days‡.”

“The cordons around Zarcozelo and Peterhoff were removed last week. We immediately visited these places, and

* Hawkins.

† Ib.

‡ Ib.

saw, for the first time, Sir William Crichton and Sir James Leighton. Both these gentlemen separately and positively asserted, repeated the assertion, and permitted us to note it, that no case had occurred within the sacred precincts of either cordon since their establishment, though the circle of demarcation was completely surrounded with the disease, and though the enclosure around Zarcozelo contained from 8000 to 10,000 souls*."

"Ever since the epidemic, the thoroughfare to Moscow has been through these little villages, which are separated by about half a verst, and contain about 200 souls. Yet, though at the village of Yshora, two versts further on, there have been several cases and deaths, and though there were so many at Colpina, there has not been a single case amongst the colonists up to this date [Aug. 8.]... The authorities say, that no precautions of any kind were taken; but it is remarked by Dr. Bowmann, that travellers to and from Moscow never halt at the colony; Yshora on one side, and Colpina on the other, being so much better resting places†."

"The large establishment composing the Academy of Military Cadets, at Moscow, was preserved by a similar plan from the scourge which was so active on all sides of it‡."

"There were 150 pupils on the officers' side (Cadets at Cronstadt), which is kept perfectly distinct from the school, for petty officers and sailors. The gates were shut on the 19th June, and as strict a quarantine as possible maintained to the 6th August (O.S.) No case amongst the pupils, who are from nine to twenty years of age§."

But if the effects of rigidly avoiding those labouring under the disease be thus remarkable, the manner in which it spreads when once introduced is not less striking. This can only be shewn by examples; and first, as to places.

"The cholera was brought to Astra-

can by ships, and it has spread itself over Russia from Astracan by the emigration of the inhabitants, principally those of the lower orders. This is the chief cause of its propagation in Russia; it has never shewn itself in any place except where it has been brought by travellers, who came from infected places. *We have not a single instance of a town, or of a village, which, without communication with houses or persons affected, has contracted the disorder.* Several places surrounded by the disease have preserved themselves from it by a rigid insulation*."

"From every thing we have been able to learn as to the progress of cholera morbus in the north of Europe—from its first appearance in the towns and villages of this country having been generally, if not always, preceded by the arrival of persons, or vessels, or both, from infected places—from the manner in which the disease has now broken out in this city [St. Petersburg], we see no other mode of accounting for its sudden appearance here than by concluding, that the harks from places on the Wolga, where the disease prevails, have brought something with them, which, disseminated in this atmosphere, has been the immediate cause of the eruption of cholera, which has just occurred‡."

"The first cases of cholera in Berlin occurred among the skippers on the boats lying on the river Spree, which flows through the town, and in houses in the immediate neighbourhood of the river. The disease has prevailed to a considerable extent in all those streets which lie along the navigated branch of the river, and whose inhabitants at the same time live in frequent intercourse with the skippers and fishermen. On the fourth and fifth days cases appeared in other parts of the city, and, in many instances, they were those of individuals who were known to have had intercourse with cholera patients, or at least with the boats lying on the river, and with the streets first infected‡."

Nor is the evidence at all less convincing if we direct our attention to in-

dividual examples of the mode of propagation. In the above illustrations, and in those which follow, we have preferred selecting instances which occurred in Europe, because, what is nearest us, both as to time and place, naturally makes the greatest impression on our minds.

"City Prison.—From the moment that the disease was proclaimed, the strictest precautions were adopted; no person was admitted without medical examination; rooms were set apart for a cholera hospital, and persons of both sexes appointed to attend the cholera cases, should any occur. Dr. Bish, who resides within the walls of the jail, and who, it must be observed, *was* an anti-contagionist, as acknowledged by himself, showed us a plan of the prison, illustrating the introduction of the disease amongst the prisoners, led us round the whole building (July 30), and communicated to us the following information from his journal, which had been most accurately kept:—“A woman had been sent out some weeks before to be treated for a syphilitic complaint*, in a public hospital. Her husband was also in confinement at the time, in a different part of the building, but remained. The woman was returned to jail, on the 23d June, O. S., with a diarrhoea upon her. She saw and embraced her husband for a moment, as she passed on to be placed in the room of observation. In a few hours she was seized with true cholera, and died that night. This was the very first case. The next persons attacked in the prison were three women in the same room with the former, one of whom had rubbed the deceased. These three died all within three days after the first. The next prisoner attacked was the husband of No. 1; he lived in a separate part of the jail. After this man, others in his room, all numbered on the plan, and registered in Dr. Bish's journal. In short, of twenty-seven attacked (fifteen dead), there is but one to whom communication cannot be traced. He was confined for a capital offence, and had less liberty than the others. There were about four hundred prisoners and attendants: the former are all well kept,

and treated with great indulgence. *None of the noble class, who are lodged in a separate part of the building, were attacked*.*”

Pensa.—“ ‘In a village of the government of Pensa, where this medical officer was sent in consequence of the breaking out of the cholera, to trace its origin and to afford medical aid, he learnt the following circumstances, which are attested by all the village authorities, and of which we are promised an authenticated copy, signed by himself:—The son of a villager, who was coachman to a nobleman, at fifty versts distance, died of cholera; the father went to the place to collect the effects of the son, and brought home with him his clothes, which he put on and wore a day or two after his arrival at his native village. He was shortly thereafter seized with cholera, and died of it: three women, who had watched him in sickness, and washed his body after death, were also seized and died of the disease: the doctor arrived in time to see the fourth case, and, finding that it spread on that side of the village, he had the common street barricaded on the side where the disease had not reached, and interdicted all communication to the two sides of the village, even for the purpose of going to church. In that side in which the disease first broke out, upwards of 100 cases of cholera occurred,—of whom 45 died, but the disease did not appear on the other side of the barricade†.’ ”

“ ‘The Navarino corvette, Captain Nachinoff, 200 men. She had been placed two miles to the eastward of Cronstadt, during the epidemic, to question and examine all craft from St. Petersburg. She had eleven severe cases of cholera, of whom eight died. Her first and second cases occurred on the 26th June, O.S. These two men belonged to the boat that examined the vessels coming from St. Petersburg, on board many of which they had been. The next men who fell ill were of those who carried the two first cases to the hospital in town‡.

Colpina.—The first patient was a

non-commissioned officer of a ship's crew, who had arrived from St. Petersburg a few days before. No. 2 was an invalided workman; this man was noted for his bad conduct, and had been ill for at least a day before he was brought to the hospital. No. 1 had been in company with him, and had been drunk the day previous to his being taken ill. The woman, No. 3, had nursed No. 2 while at home; so that there appears a strong case of communication of the disease, which cannot be traced further*."

"A physician (Dr. Calow), who had attended cholera patients, being at the time in bad health, and labouring under diarrhoea, died of cholera; on the day following, his landlord (Mr. Steibelt), died; a day afterwards, two children of the landlord died, and the servant-maid was taken ill of cholera, and recovered. The landlord's wife had been removed to quarantine. There have been no more cases of cholera in this street or its neighbourhood†."

Instances of this kind might be quoted without number; but if what we have given do not convince our readers that the disease is transmitted from one person to another, probably no multiplication of the same kind of evidence would avail.

There is, however, one point connected with this part of the question which it may be necessary to set right before we proceed farther. It has been said, that if cholera were contagious, a larger proportion of medical men than of others ought to take it. Hear what happened at St. Petersburg:—

"Fifteen hospital physicians had been attacked, and six had died of cholera up to the morning of the 13th [July] instant, N. S., out of 264 medical practitioners of all descriptions, who were in St. Petersburg at the breaking out of the present epidemic‡."

Was it by chance, we ask, that the first fifteen medical men affected with cholera were hospital physicians §? But again—

"Though we have not yet obtained official returns of the number, we are satisfied, from the statements we have personally received in the numerous hospitals we have visited, that the proportionate number of attendants, of all descriptions, on the sick, who have been taken ill with cholera, is fully greater than that of the medical men*."

Besides—

"There were 70 attendants of all classes employed about the cholera hospital of the Foundling Hospital, of whom 15 were attacked; two prescribing physicians, one attacked. Dr. Duppe [the resident physician] was seized on the 22d [June, O.S.] He had seen no sick before the first case of the *garde malade* already mentioned†."

Such are the chief considerations which, after the most scrupulous investigation, and in opposition to preconceived opinions, have convinced us that cholera is contagious. Several very important questions connected with the circumstances which facilitate or retard its propagation remain untouched; but we have already trespassed too long on the patience of our readers, and must leave further observations for another opportunity. We shall therefore add but one sentence more. The first step towards arresting a disease consists in detecting its mode of spreading—if Cholera does so by contagion, as we hold to be the case, the means of checking it are obvious; if it depend on any thing in the air around, or in the earth beneath us, then no human means will avail aught in arresting it;—therefore our view, as it is the more rational, is also the more safe and consolatory; and let it be kept in mind that, even if we be wrong, still no danger is incurred to the public safety by adopting our opinions; but if the anti-contagionists be wrong, and their principles followed, the peril is imminent, the evil incalculable, and the

extension and permanent residence of the malady in this country, its naturalization among us, will be the inevitable result; just as the same ignorance, or disregard, of the mode in which the disease is transmitted, led to its overrunning the whole of India, in which country, at the end of fourteen years, it still continues to abide.

[See Postscript, page 214.]

COMPARATIVE MORTALITY OF CHOLERA.

THE mortality of cholera has been very different in different places. According to an account given in the Russian State Gazette, the number cut off by the disease out of every 1000 inhabitants, during the first 48 days of its visit, has been:—at Lemberg, 51; Mitau, 34; Riga, 31; Posen, $16\frac{1}{2}$; Petersburg, $12\frac{1}{2}$; Königsburgh, $11\frac{1}{2}$; Elbing, $9\frac{1}{2}$; Dantzic, $8\frac{1}{2}$; Stettin, $5\frac{1}{2}$; Berlin, 4.

CHOLERA AT BERLIN.

IF it be recollected that the capital of Prussia contains 225,000 inhabitants, besides a strong garrison, the ravages of cholera in that city will not seem to be so very frightful. From the 31st of August to the 10th of October, the daily number of persons attacked was from thirty-five to forty; and the whole number during that period amounted to 1100, of whom 233 were cured, and 665 died—the rest still remaining under cure. Of the garrison, no more than ten soldiers were attacked, but eight of them died. The physicians and hospital attendants have been generally safe.—*French Paper.*

PREMATURE INTERMENT IN CHOLERA.

THE bodies of persons, apparently dead of cholera, have been in some instances observed to move. M. Londe, President of the late Warsaw Commission, has expressed his belief that many have been buried alive in the complaint.

SINGULARITIES.

AMONG the correspondence read at a late sitting of the Academy of Sciences,

in Paris, were the following singular items:—1. A cure for the cholera, by a M. Dutertre, who offers to lose his head at the Place de Grève if his remedy be not found superior to all that has ever yet been tried; 2dly, a letter from M. Garnier, announcing his discovery of the quadrature of the circle; 3dly, a letter, accompanied by a pretended *head of a flying dragon*, which M. Cuvier at once recognized to be the *head of a pig*; and, 4thly, a copy of verses on a new remedy for cholera!

ANALYSES & NOTICES OF BOOKS.

Reports of Medical Cases. By DR. BRIGHT. Price 9*l.* 9*s.*

[Continued from page 158.]

PRESSURE OF THE BRAIN resumed.

THE next case is remarkable for the unusual rapidity with which it proved fatal. Mr. N—, aged 57, of spare habit and anxious disposition, enjoyed good health up to July 1st, 1830. He had been much fatigued, and went to bed at half-past ten, having taken a moderate supper. About half-past one he awoke sick, but seemed to be relieved by vomiting. His wife, however, was alarmed by his mode of breathing, and rang for assistance, when he was found in a deep apoplectic seizure; and before medical assistance could be procured he was dead—his decease occurring within twenty minutes from the commencement of his attack. The lateral ventricles were found distended with a large quantity of semifluid blood, which raised up the velum interpositum from the thalami. From this membrane the hæmorrhage seemed to have taken place, as it was rent at one part. The corpora striata seemed to be broken down in their substance to the extent of a fifth of an inch, and beyond this depth spots of ecchymosis were perceptible. The commissura mollis was torn, and the blood had descended into the third and fourth ventricles: the entire quantity might be above three ounces. The action of the heart had always been very forcible, but that organ appeared healthy in its texture, with the exception of a slight de-

posit in the aortic and mitral valves, but not to such an extent as apparently to interfere with their function. The coronary arteries were much enlarged.

In the preceding case the death took place with unusual rapidity for apoplexy, though still it was not so instantaneous as in rupture of the heart, or great vessels.

In the case which follows, death took place in an hour and a quarter from effusion of blood near the corpus striatum, tearing the texture of the brain and bursting through the arachnoid. The hæmorrhage appeared to have been copious and unrestrained, owing to the softened condition of the brain at the point where it occurred. Numerous other cases are given of apoplexy dependent upon effusion of blood, but in none did the fatal termination take place so soon, and in some it did not occur for several weeks. These cases were, in general, instances attended with some disease of the vessels. In two instances, where the patients had suffered repeated attacks of hemiplegia, affecting articulation and deglutition, and proving fatal at the end of several months, disease was found at the posterior part of the corpora striata. In another there was hemiplegia of the left side, and the cerebral lesion was not on the opposite but on the same side. As the case is short, we shall insert it.

Hemiplegia on the left side, with Cerebral injury on the same side.

"John Walker, aged 33, was admitted into Guy's Hospital October 14th, 1829, labouring under a severe attack of bronchitis; his countenance purple, his breathing very difficult, and his legs œdematous. He had considerable hesitation in his speech, owing to a paralytic affection of the mouth and tongue; and his left hand and arm were weak and obviously paralytic, though not to such an extent as to be useless. On inquiring from his relatives, we learnt that the whole left side was paralysed about a year ago, that the affection was sudden and for some time severe, but that he gradually recovered the use of his limbs to the present time. He survived only three days after his admission, and his death was quite sudden, so that he had spoken to the nurse within a few minutes of his dissolution.

"*Setio Cadaveris.*—The dura mater was perfectly natural. The arachnoid and pia mater shewed a good deal of vascularity, but of purple blood, arising from congestion;

very slight effusion beneath these membranes, which were stript easily from the convolutions, except on the lateral and outer part of the left hemisphere, where it was found impossible to detach them without lacerating the brain, to which they were glued by a thin opaque yellow flake of deposit, like fibrin: immediately below this adhesion, and extending to the middle of the corpus striatum, was an opaque portion of the brain considerably harder than the brain itself, plainly shewing in its centre that it was the scar of an apoplectic cyst, surrounded by hardened parietes. The cavity in this was scarcely so large as half a small French bean, containing a little softened curd-like substance; but the derangement from the injury evidently extended from the middle of the corpus striatum, the structure of which was much disturbed, quite to the surface of the middle lobe.

"The whole of the remaining parts of the brain, and more particularly those of the right side, were most carefully examined, but without finding the slightest trace of disease. The medulla oblongata was so cut into, that we did not ascertain whether there were any peculiarity in the decussation of the fibres."

There is every reason to believe, with Dr. Bright, that the diseased portion of brain above described was constituted by the remains of the apoplectic cyst, which had undergone a kind of cicatrization. A case in which the lesion and paralysis were on the same side, is recorded by Morgagni, Lib. I. Epist. 2. § 16.

The author next introduces some cases, illustrative of the effects of pressure acting suddenly, yet not proving immediately fatal. It is upon cases of this sort, which fortunately are not infrequent, that all our hopes must be founded of being able to prolong life, and often to secure even a pleasurable existence after the occurrence of severe attacks and of very unfavourable symptoms. Sooner or later, however, if their subsequent history be traced, it will be found that the disease has recurred in most instances, and ultimately proved fatal.

A woman, aged 33, had experienced, during some weeks, headache, vertigo, and occasionally dimness of sight, for which she was bled, and blistered on the neck, with very little relief. Upon awaking one morning, she found she could not move her left leg and arm as well as usual, and, in short, she proved to be afflicted with all the symptoms of

partial hemiplegia. She suffered much from pains in the side affected, particularly in the joints of the leg and arm. Pulse 108; tongue covered with white fur, moist, and slightly drawn to the left side. She attributed her illness to exposure to cold and wet. She got better in the hospital, but her partial paralysis was by no means cured when she was discharged. Those pains in the affected limbs, sometimes (and with correctness) ascribed to rheumatism, were also observed in two other cases; they appear, however, to be rather connected with the affection of the nerves on which the paralysis depends.

A man was taken to Guy's Hospital, who, while rowing the day before, was suddenly seized with insensibility, and, on recovering himself, found that he had lost the power of his right side, and was unable to articulate. He had been labouring under severe cough and dyspnoea for six weeks, and there can be little doubt but that this pulmonary disorder laid the foundation for the effusion of blood in the brain, which was immediately induced by the exertion he was making at the moment. By cupping in the neck, keeping the bowels open, and by the use of a combination of squill, grey oxide of mercury, and a little opium, he was enabled to go home in a few weeks much relieved.

Another instance of paralysis from cerebral congestion, arising from obstructed circulation in the lungs, but augmented by habitual constipation, is given by Dr. Bright, in the case of a woman who had been long accustomed to a most severe asthmatic affection, which used very often to prevent her lying down at night. She was also subject to occasional pain in the head, giddiness, and sickness. While suckling a child, some six weeks before she came to the hospital, she suddenly heard of an accident having happened to her son, upon which she fell into a sort of hysteric fit. This was followed by a loss of power and sensibility in the left thigh, and the arm of the same side was similarly affected. A few days after, the right leg became numb and powerless, so that she could no longer support her weight. By the use of the aloes and myrrh pill, and attention to her bowels, which were habitually confined, she was so much improved that, in about ten days, she could rise from

her bed and walk some distance; and she went on improving to such a degree that, though not completely restored, she was allowed to leave the hospital, at her own request.

We shall just give an abstract of one case more before we proceed to the author's general inferences. A thin, middle-sized man, 46 years of age, whose occupation was to work the steam-engine of Barclay's brewery, was admitted into the hospital, affected with hemiplegia. For some time previous he had suffered from occasional headache and vertigo; but it was not above two hours before his admission, that, as he was walking, he felt his right foot become very heavy, and then his right hand; his articulation also became very indistinct. Sensibility was very obscure on the whole of the affected side; indeed it might be traced accurately to the middle line of the body and head, including the ear and cheek. The mouth was drawn to the left side; the speech indistinct; the pupils acted naturally when light was brought to them; his intellects quite undisturbed; bowels costive; head more free from pain than for a long time previous to the attack. He was bled and purged freely, cold applications put to the nape of the neck, blistered, &c. Under this mode of treatment he gradually improved, and at the end of ten weeks left the hospital pretty firm on his feet, and with some power of his arm. It was ascertained, however, that some weeks after his return home he had another fit of apoplexy, in which he died. The history of this case, as Dr. Bright observes, is not very mysterious: there was here clearly long irregular distribution of blood, probably accompanied by diseased vessels; extensive sanguineous effusion into the left hemisphere, perhaps injuring the posterior part of the corpus striatum. This effusion having ceased, the process of reparation went slowly on; some fresh excitement induced increased flow of blood; the injured vessels again gave way; the effusion became more extensive, and the blood probably burst its way into the ventricles; but the exact circumstances of the patient's death are unknown. "Had he been contented," says Dr. B. "to remain quiet for some months longer, it is very possible that the injury would have been more completely heal-

ed, and that, with care, he might have lived many years; but his arm would never have been perfectly restored."

General Observations on Apoplexy.

With regard to apoplectic attacks generally, it will be observed, and the observation is borne out by a copious induction from the cases adduced by our author, that, in the first place, neither age nor sex affords security: a majority, however, of those attacked have been males, and these chiefly above the age of forty, and many above sixty years of age. The spare and tall, as well as the short and robust, have been subject to the disease, but not in equal proportions; the plethoric frame certainly seems to predispose to that irregular action of the arterial system, and to that tendency to congestion, on which apoplexy and paralysis so essentially depend. Intemperate and irregular habits of living have a large share in preparing the way for an attack; and accidental blows appear frequently to act as strong predisposing causes. Anxiety, mental exertion, and sedentary habits, likewise decidedly predispose. Many severe attacks occur without any previous symptom sufficient to excite alarm; but much more frequently some subordinate seizures have been experienced—momentary loss of consciousness, giddiness, slight defects in the sensibility of parts, frequent irregular or convulsive actions; and at other times sensations of beating within the head, or peculiar noises, or defective vision. On inquiring into the previous history, we not unfrequently find that strong evidence exists of disease in the heart and large vessels, or of great obstruction in the lungs, or of such derangement in the kidneys as is calculated to interfere very essentially with the healthy discharge of other organs.

"When the decided attack has taken place, it varies greatly in extent and severity: sometimes it is attended with violent pain in the head; sometimes there is not the slightest pain; sometimes it assumes the form of complete apoplexy, the annihilation of all consciousness, the extinction of all sensation, the loss of all voluntary motion:—for a few minutes, or a few hours, the retarded pulse bespeaks the difficulty with which the heart and arteries maintain, by their involuntary actions, the labour of circulation, and the ster-

torous sound or impeded breathing betrays the inactive condition of those muscular parts through which the involuntary powers are called upon to force the air in the process of respiration; and these soon prove insufficient to maintain life. At other times the apoplectic condition, though well marked, gradually subsides; or frequently the state of insensibility continues for a few minutes only; while in some attacks the consciousness is never destroyed. But though the apoplectic state should not exist, or though the consciousness should have returned, yet if effusion of blood have taken place, paralysis will generally remain. The extent of this paralysis will vary almost indefinitely; it frequently affects both the motion and the sensation of the same part; sometimes, however, the motion, and sometimes the sensation, suffers in the greatest degree; and occasionally the sensation of one part and the motion of another are more strikingly influenced. Hemiplegia is by far the most common form which paralysis assumes from effusion of blood within the cranium. I have, indeed, never met with a decided instance of paraplegia from this cause: occasionally one leg or one arm will be affected, without the other limb on the same side suffering materially; but those forms of paralysis, which occupy almost exclusively the two upper or the two lower extremities, very rarely result from the sudden effusion of blood in the brain. Cases occur where paralysis of the two lower extremities has appeared to depend on other disease or injury in the brain; but of these we should always be somewhat sceptical, from the obvious sources of error to which they are liable; amongst which, the unobserved or the unsought diseases of the spinal cord and its membranes are the most to be suspected. Defective articulation and deglutition, either alone or as attendants upon hemiplegia, are likewise common results of apoplectic seizures. Occasionally great pain is experienced in the affected limbs, while at other times a sense of numbness alone is felt. The powers of the mind generally suffer in some degree, but this varies greatly:—sometimes the mind evinces great irritability, and sometimes a childish tendency to excitement, and a trifling turn quite inconsistent with the former disposition, or with the present situa-

tion of the sufferer:—at other times the patient falls into a dull state of imbecility; while cases occur in which the affection of the mind is so slight, that it is only by close examination it can be detected.”

Treatment.—The most important of all remedies in apoplexy, is the judicious employment of bleeding. It is clearly indicated for the removal of congestion in the brain, or with a view of checking the hæmorrhage, or to reduce the general plethoric condition of the system. When apoplexy simply depends upon congestion in the brain, a large and free abstraction of blood almost immediately effects a cure of the disease. When rupture and effusion have actually taken place, and the slow and labouring pulse shews to what a degree the vigour of the nervous system has been depressed, it is still our duty to bleed, and to bleed largely. Small bleedings, however, will rather do mischief, by increasing the chance of hæmorrhage as the force of the circulation is increased. After bleeding, the pulse must be watched, and if it increase in rapidity, still maintaining considerable force, we must bleed again; but if we find that after two free bleedings, in which we have abstracted forty or fifty ounces of blood, no decided benefit is derived, we must remember how much it behoves us to husband the small remaining stock of vital energy, which, owing to the patient's habits of life perhaps, had been, even previous to this abstraction, greatly diminished. Cupping is to be employed only after venesection has been fairly tried; experience leads us to think favourably of the practice, and perhaps by applying the glasses either to the temples or behind the ears, we may more immediately, and often very expeditiously, draw blood from arterial branches of considerable size with the most decided benefit. How far the application of cold to the head is generally useful, admits of some doubt, as a means of checking hæmorrhage when it is taking place from parts which have strong sympathy with the skin, or are almost continuous with it, we have the strongest proofs of its efficacy. Epistaxis and uterine hæmorrhages are good examples of this; though in apoplexy the circumstances are not precisely analogous. There is much danger, too, it ought to be observed, in a long-continued application of cold to the head in apoplexy, when there is reason to

apprehend a tendency to delay in the circulation, or probable congestion. Where congestion exists, the sudden application of cold is most desirable—and sometimes even when hæmorrhage is taking place within the substance of the brain; but it would undoubtedly be hazardous, as Dr. Bright very properly observes, when employed with this view; for it might throw the impulse from the external to the internal circulation, and thus rather increase than diminish the extravasation of blood.

We give the remainder of Dr. Bright's treatment in his own words, without abridgment:—

“Purgatives are of great importance in every stage of these diseases. It very frequently happens that the immediate cause of the attack is the neglected state of the bowels, and nothing tends more to favour cerebral congestion than a loaded condition of the alimentary canal. When the patient lies under the first impression of the attack, he is often quite unable to swallow medicines, in which case the oil of croton is the most active and appropriate remedy of this class. We should be careful not to administer calomel before the powers of deglutition are sufficient to ensure its being swallowed. I once saw most serious consequences result from this; for having put five grains of calomel on the tongue, and attempted to wash it down with a cathartic draught, the calomel, instead of passing into the stomach, remained, moved about by the tongue, and produced in a few hours the most alarming ptyalism, in which the tongue was forced out of the month, and it was necessary to scarify it deeply before it could be returned within the teeth. If, however, the patient can swallow well, a dose of calomel with extract of colocyath, followed by castor oil, is a very proper purgative. Cathartic injections may also be used with much advantage. In some cases, where the paralysis has been less complete, where paraplegia has occurred, or where there has been a combination of hysteric irritation with the paralytic affection, purging has sometimes been the chief means of cure.

“Diuretics are likewise of great utility; indeed the importance of attending to the action of the kidneys may easily be inferred from the perusal of the foregoing cases, in which the connexion between the apoplectic state and their defective action has been so

frequently traced: and those who have seen much of diseases cannot be ignorant, that even the undue retention of the urine in the bladder is liable to produce great cerebral disturbance; a fact which is proved continually during the prostration of fever, and in a still more striking manner by the state of coma in which strictures of the urethra and retention of urine often terminate.

"Blisters to the nape of the neck and the counter irritation produced by the liniment of tartarized antimony, or the continued discharge from a seton, often promote the cure when the first severity of the disease is passed away, and when we have reason to suppose that morbid action is interfering with the healing processes of the system.

"The time, however, soon arrives when it is necessary to give tone and even to stimulate the torpid nerves, which appear in a certain degree, even after they may be considered as organically capable of resuming their functions, to continue inactive from habit; and this is very much the case in the subordinate attacks of paralysis, where no very extensive organic lesion has occurred. It is at this period that the balsamic preparations are of utility, and that the mineral tonics are employed with advantage: the sulphate of zinc and the arsenical solution act occasionally very well. The *nux vomica* is a remedy which has long been employed during the state of nervous torpor which attends the tedious convalescence after paralytic attacks, and of late the more active principle of that drug, the strychnia, has been substituted: it tends to excite an action in the nerves, which, though not in itself a healthy action, may counteract the morbid state to which they are reduced. In a case of local paralysis, I have applied this powerful remedy in doses of the eighth, the quarter, or half a grain, to a blistered surface, with the effect of producing spasmodic action through the paralysed muscle, and I have sometimes administered it internally with advantage. But cases of hemiplegia from the rupture of vessels are not those in which this remedy holds out the greatest prospect of success, though with caution it may be employed in the advanced stages of convalescence, with safety at least, and sometimes with benefit. Exercise of the affected parts, and friction, are of use; and, by degrees, moderate

and cheerful occupation of mind, avoiding excess and anxiety, will rather promote than retard recovery."

Warning to the British Public against the alarming approach of the Indian Cholera. By SIR GILBERT BLANE, Bart. F.R.S.

THE benevolence which dictated the publication of this little tract will, we have no doubt, be generally appreciated. The venerable baronet, filled with just apprehension for the safety of his fellow-countrymen, lifts his pen for the most praiseworthy of all purposes, and imparts his advice with the earnestness of a dying injunction. He endeavours to impress upon them the horrible nature of the malady with which they are threatened; gives a short sketch of its history; distinctly expresses his belief of its contagious nature; and concludes with some plain practical suggestions for its treatment when it is among them. As we heartily concur with Sir Gilbert, in thinking this to be one of the most alarming visitations with which England has had to contend for many years, and that too much pains cannot be taken to impress this opinion upon the public mind, accompanying that impression with salutary advice, we will not stay to find fault with some minor points which struck us in the perusal, but recommend the "Warning" generally, to the notice of all.

Cholera, its Nature, Cause, Treatment, and Prevention, clearly and concisely explained. By CHARLES SEARLE, Esq. of the Hon. East India Company's Madras Establishment.

WITHOUT attending to the rather uncomplimentary reflection on medical critics, thrown out by Mr. Searle in his Preface, we proceed to notice the substance of his pamphlet as practically as he could wish, premising merely, that, concise and clear as his little work, on the whole, undoubtedly is, it could be rendered still much more so by leaving out the third and fourth chapters, which profess to treat of the "cause of cholera," and of the "operation of the cause in producing the phenomena, &c." We have not patience for dwell-

ling on those pages of a writer professing practical, which treat *de non apparentibus vel non existentibus*; suffice it, for the benefit of those who may not see the work, to mention what the author holds to be the "one essential agent, and immediate cause of the disease;" which is, "*a mephitic vapour or miasm, of the nature of, if not identical with, malaria, in the common acceptation of the word, which being received into the system by respiration, contaminates the blood with its poisonous agency, and, in common with the other poisons of a sedative class, of which it is one, operates immediately and specifically upon the capillary vessels, in depreciating and arresting their functions; and hence, as they enter into the composition and structure of every organ and part throughout the system, and as their function is nutrition, secretion, calorification, and, in short, all that appertains to the life and health of the part and system in general, it necessarily follows that the depreciation of their action is attended with debility of all the functions, &c. &c.*" We fear this will not pass for a good specimen of the author's ability in getting up a useful popular pamphlet; we therefore turn to something really more valuable, or at least less questionable and obscure.

Mr. Searle divides the symptoms of cholera (the cholera, as it appeared in Poland, we presume—the pamphlet is dated from Warsaw) into three stages. In the first, or that of invasion, the patient feels giddiness, and disturbance of the stomach and bowels; then vomiting comes on, with evacuations from the bowels of a sero-mucous or barley-water-like appearance; prostration of strength, twitches, pain, numbness and cramp in the extremities; sunken dusky countenance, ringing in the ears, cold skin, and feeble pulse. In the second stage, or that of excitement, inward burning heat at the pit of the stomach, attended with great thirst; pulse sharp and frequent; head and trunk somewhat more warm; tonic spasms gradually involving the muscles of the belly and chest. The third stage, or that of collapse—which often follows the first stage, without the intervention of the second, or that of excitement—is characterized by the cessation of the spasms; livid extremities; cold clammy skin; countenance death-like; coma and dyspnoea—with death ensuing in ten or twelve, but

generally within eight-and-forty hours from the period of invasion. There is considerable variety, however, in the symptoms, as they appear in different individuals and under different circumstances: the spasms are sometimes not distinguishable; sometimes a mortal coldness comes on from the beginning, and the patient dies without a struggle.

We have, on a former occasion, given some of Mr. Searle's peculiar opinions with regard to the exhibition of *common salt* in this disease: we may now add, on this head, that he continues to recommend that practice most strenuously, as the best beginning of the treatment.

"As a deranged state of the stomach is, I am of opinion, no unfrequent exciting or predisposing cause of the attack, or if not, as indigestion invariably succeeds to it, as a general rule, I think it always advisable to commence the treatment by evacuating the stomach, whether the patient has vomited before or not. With this intention let the patient drink freely of warm water, or (which I am of opinion is better, as it operates almost instantly, and more perfectly accomplishes the purpose, and is always available, and from its stimulant and mild aperient qualities is useful also with these intentions)—a *large table spoonful of common culinary salt*, (muriate of soda) dissolved in half a pint of hot water, and drank as warm as it well can be: should it fail in producing the desired effect, which however is but seldom the case, a second dose may be repeated five minutes afterwards. Prior to the emetic, I think it however advisable, whenever the state of the patient admits of it, particularly if there be pain in the head, or oppression about the præcordia, that the patient be bled from a small orifice, in the recumbent posture, to a moderate extent, as this tends immediately to the relief of these symptoms, which are dependent upon accumulation of blood in these parts; and the emetic following the bleeding to the restoration of an equilibrium of the circulation."

We need not follow the author in the other particulars of his practice in cholera, which are those generally recommended by most writers, and already detailed with sufficient minuteness in our pages. Calomel he prescribes in large doses, because, says he, "in effect, in this disease large doses are but equal

to small ones under ordinary circumstances, from the diminished absorbing power of the stomach and susceptibility which assists to its influence."

Twelve grains, he thinks, ought to be the first dose, "which being simply placed upon the tongue, should be washed into the stomach by a cordial; and a very suitable one is a dessert or table spoonful of brandy, with double the quantity of hot water; and the same dose of calomel should be repeated every hour or two, according to the urgency of the case, and commensurate with the improvement of the patient in smaller doses, should it be continued, till bilious stools and urine are restored, when it may be given in conjunction, or alternately with some mild aperients, till healthy secretions are established."

In his directions with regard to articles of diet and sustenance craved by the patients in cholera, we fear Mr. Searle is too indulgent in consulting so freely the wishes of the sufferers, notwithstanding that he pleads the observation of twenty years practice of medicine to bear him out in the proceeding; but we highly approve of the greater part of his treatment, and more particularly of the sensible remarks which he offers for the benefit of those who are wise enough to take timely precaution. We need scarcely add, that he advises temperance and moderation above all things; and the following hint ought not to be neglected:—

"In cholera times, it is particularly advised that you should not leave home in the morning with an empty stomach; a cup of coffee, with or without a tea-spoonful of brandy in it, and a biscuit, is indispensable, if too early for breakfast. And a light supper, with a little spirits and water, is no bad thing before going to bed, which should be early."

We bar the supper, however; the cup of coffee and the biscuit, as a stay before breakfast, may do very well.

The pamphlet concludes with (we think very unnecessarily) a reiteration of the author's continued adherence to his opinion that the disease is not contagious. We take leave, with regard to this point, to refer him to our leading article in the present number.

Practical Remarks on the Disease called Cholera, which now exists on the Continent of Europe. By JOHN GOSS, M.R.C.S. and late Assistant-Surgeon in the Hon. East India Company's Service, Bombay Establishment.

On Cholera Morbus. By MEDICUS.

IN the first of these productions, the only thing we discover worthy of notice, is the author's announcement of the strong acidity of the contents of the stomach when ejected in cholera. "I was sent for," says Mr. Goss, "to an old native woman, who was labouring under all the symptoms of the second stage of the disease. I applied carbonate of soda to the fluid she vomited, which made it effervesce most powerfully; I therefore administered about a drachm of the soda, with ten or fifteen grains of the carbonate of ammonia." The woman recovered, and the author, of course, thinks himself justified in giving the soda plan the strongest recommendation. But the means on which he would place his whole reliance are these—bloodletting to the fullest extent that the system will bear—constant frictions, with a camphor cantharides and turpentine liniment—a mustard poultice to the abdomen—soda and ammonia as above mentioned—and, finally, calomel and jalap. Some absurd arguments are ventured in favour of the non-contagionists.

The brochure of *Medicus* is a catch-penny—ill written and ill got up. In that part where the writer proposes his treatment, he says, he *should not be disposed to cavil with the universal hot bran cataplasm of the Russians!*—though perhaps a vapour bath might be a *more elegant* substitute; nor does he think that in cholera *the bowels ought to be neglected*, for which reason he prescribes opium; and "for the safe administration of that drug," combines two grains of it with "a scruple of calomel, washed down with a camphor draught."

Remarks on the Cholera Morbus; containing a Description of the Disease, its Symptoms, Causes, and Treatment, &c. By H. YOUNG, M.D. formerly of the H. E. I. C. Medical Service in Bengal.

At the present moment our readers will naturally expect us to take notice of all

most works on the engrossing subject of cholera. The one whose title we now give presents no particular claims to their attention. The history and symptoms are described with tolerable perspicuity, but these are now familiar to all, and there is nothing in the details before us of any novelty. The author supports the doctrine of contagion, and recommends the same general methods of treatment as the rest of his Indian brethren.

THE LATE DR. BECKER'S ACCOUNT OF THE CHOLERA AT BERLIN.

Copy of a Report of Dr. Becker, of Berlin, to Mr. Chad, his Majesty's Minister in that capital.

Oct. 12, 1831.

THE comparatively small number of persons attacked with cholera in the city of Berlin, during the first month of the prevalence of this disease, seems to be owing chiefly to the following causes:—

1. The manner in which Berlin is built, compared with other populous cities. It has few crowded and narrow streets, and a great proportion of the lowest classes of the population inhabit the outskirts of the town, where the streets are large and distant from one another.

2. The attention which has before and since the appearance of the disease been directed to the necessity of *avoiding cold and intemperance*. The advice given on this subject by the civic authorities, as well as by the medical men, which, as everybody can read here, must have reached all classes of the population, has been practically assisted by food and clothing distributed among the poorest inhabitants. The almost complete immunity of the garrison of Berlin from cholera is chiefly to be ascribed to the pains taken to give the soldiers additional warm clothing, and to force upon them a healthy diet.

3. The measures taken to prevent the spreading of the contagion. The method adopted is, when a case of cholera occurs in a family, to put those who have had intercourse with the patient, as well as the patient himself, under a sort of quarantine: this lasts for five days after the patient has died, recovered, or been removed to an hospital. It

is left to the choice of the friends whether they will pass this time in their habitation, or go to houses appropriated to the purpose of receiving them (*contumaz, anstalten*). During the time the rooms in which the cholera has prevailed are cleaned, and 'disinfected' with chlorine*.

All these measures are directed by the local committees, of which there are 61 in the city and suburbs, consisting of respectable inhabitants, medical men, and a police-officer, and having in their service men who devote themselves to nursing the sick, and preventing intercourse with other persons. These servants of the committee are generally lodged in particular houses, where they are always to be found. It cannot be said, however, that these regulations are, in all instances, rigidly adhered to; they are often neglected, owing to the prejudices of the patients and their families, who conceal the disease; the remissness or connivance of the medical men, who do not wish to cause inconvenience to themselves and their patients; and the inactivity of some of the committee.

Experience has shewn that the spreading of the cholera has been most efficaciously prevented when the patients have been *immediately removed to an hospital*, and where those who had lived in the same room with them also left the infected house, and returned to it only after it was cleaned and aired. This measure having been adopted wherever circumstances admitted of it, may, in fact, be regarded as the chief cause of the very moderate extent to which the cholera has till now prevailed.

In reply to the other queries put, the following answers may be given:—

1st. What description of persons has most suffered from the disease at Berlin?

The great majority of persons attacked with cholera in Berlin consists of those who, on the one hand, are exposed to the usual causes of disease, viz. cold, fatigue, and particularly intemperance in food and drink, or are labouring under previous disease, particularly diarrhoea; and, on the other hand, are, by their business, or by chance, brought into intercourse, direct or indirect, with those already attacked by the disease,

* Of the superior efficacy of this substance, however, there is no evidence.

and with their dead bodies. Of course the greatest number of patients occur in the lower orders, who form the bulk of the population; but there have not been few instances among persons in easy circumstances; in them also, previous disease, intemperance, fatigue, or anxiety of mind, have generally, although not uniformly, preceded the disease.

2dly. Whether the disease was confined, for any length of time after its appearance, to one street or one district of the city?

The first cases of cholera in Berlin occurred among the skippers on the boats lying on the river *Spree*, which flows through the town, and in houses in the immediate neighbourhood of the river. The disease has prevailed to a considerable extent in all those streets which lie along the navigated branch of the river, and whose inhabitants at the same time live in frequent intercourse with the skippers and fishermen. On the fourth and fifth days cases appeared in other parts of the city, and, in many instances, they were those of individuals who were known to have had intercourse with cholera patients, or at least with the boats lying on the river, and with the streets first infected. In the part of the city chiefly inhabited by people in easy circumstances (Friedrichstadt) such cases generally remained solitary, and the disease did not spread in the streets where it had thus appeared; in those districts, on the other hand, which are peopled by the labouring classes (in the centre of the town, and in the eastern suburbs), the disease once having occupied one house of a street, was observed to attack other houses successively. Three weeks after its commencement the cholera had spread in all directions, without any regard to situation, high or low, damp or dry, or to exposure northern or southern, eastern or western, but occurring in solitary instances only in the Friedrichstadt, whilst it found numerous victims in four or five other quarters remote from one another, and inhabited by the poor.

3dly. Whether, when the disease attacked one member of a family, the other individuals in the same family suffered from it?

This is the case so frequently, that it may almost be considered as the rule, and the contrary as the exception, unless the patient be removed from his

family. It is not possible to give any numeric returns of the recurrence of the disease in families, but the following is a statement of its re-appearance in the same houses where it had shewn itself:—

From August 29th to September 26th, there have been reported cases of cholera in Berlin, 770. During that period, a second case has happened in the same house where one case had been reported:—After one day, 65 times; two days, 34 do.; three days, 23 do.; four days, 16 do.; five days, 21 do.; six days, 7 do.; seven days, 3 do.; eight days, 2 do.; nine days, 0 do.

In order to illustrate this point, it may not be superfluous to mention some instances of the recurrence of cholera in the same families and buildings:—

1. A physician (Dr. Callow), who had attended cholera patients, being at the time in bad health, and labouring under diarrhœa, died of cholera; on the day following, his landlord (Mr. Steibelt) died; a day afterwards, two children of the landlord died, and the servant-maid was taken ill of cholera, and recovered. The landlord's wife had been removed to quarantine. There have been no more cases of cholera in this street and its neighbourhood.

2. A family, living on the river side, consisting of husband and wife, four children, and a servant-maid, were all successively attacked with cholera; only the husband and one child survived.

3. In a house (Alte Jakobstrasse, 66,) the following cases of illness have occurred:—1. Sept. 7th, W. M. 27 years of age, seized by cholera; recovered.—2. 8th, Miss M. 32 years of age, with vomiting and purging; recovered after twelve hours.—3. 11th, A boy of two years and eight months, son of a cutler, cholera; died on the 12th, after eleven hours' illness.—4. eod. A journeyman of the cutler, vomiting and purging; recovered.—5. 13th, The child of a tailor, aged two years and nine months; died of cholera after nine hours' illness.—6. 15th, An apprentice of the cutler, vomiting and purging; recovered.—7. eod. The man who had been in attendance on No. 5 took the cholera, and was sent to the hospital.—8. 16th, Another apprentice of the cutler, vomiting and purging; recovered.

4. The *workhouse* (arbeitshaus), a large building occupied by a numerous

poor population, had a cholera patient, on Sept. 3d, *five* days after the appearance of the disease in the city: the following cases successively occurred in this building:—Sept. 3d, 2 cases; 5th, 2 do.; 11th, 1 do.; 15th, 1 do.; 16th, 5 do.; 17th, 7 do.; 18th, 6 do.; 19th, 9 do.; 20th, 4 do.; 21st, 6 do.; 22d, 2 do.; 23d, 6 do.; 24th, 3 do.; 25th, 2 do.; 26th, 4 do.—60 cases.

Immediately beside the workhouse there is another building (Familienhaus), inhabited by a great number of very poor families, who there find employment of various kinds: here the disease did not show itself till September 8th, *five days after the first case in the workhouse*: from that day to the 26th Sept. 27 cases occurred in this house.

It may finally be stated, that the manner in which the cholera has appeared and spread in Berlin, perfectly warrants the conclusion, that this disease is always produced by a peculiar human effluvia, which in its mode of generation and effusion shows some analogy with that of the *common typhus fever of Great Britain*, but extends its deleterious effects to a limited number of persons only, who are rendered eminently susceptible by cold, intemperance, fatigue, fear and anxiety, diarrhoea, and other previous diseases.

(Signed) F. W. BECKER, M.D.

Berlin, Oct. 5, 1831.

PARISIAN BOARD OF HEALTH.

Extract from the Instructions given by the Central Commission of Health, in Paris, to the Minor Commissions of Districts and Parishes (d'arrondissement et de quartier).

In the event of the arrival of this awful epidemic, it will behove all good citizens to combine their efforts with those of government to purify the city as perfectly as the localities will permit.

The commissions are composed of medical men, persons of professional distinction, so selected as that each may be employed in that line for which his talents and his experience adapt him. To these are added persons unconnected with the profession, but whose standing in society is most respectable, and who have more time and local knowledge to

assist and direct the proceedings of their colleagues. The civil power has received orders to second the business of the commissions.

The parish commissioners are to visit *every house* in their parish, and point out to the inhabitants whatever they find amiss, warning them of their danger and of the propriety of setting all to rights before the police interfere. In these visits it will be particularly necessary to ascertain the state of the privies, leads, gutters, and channels into which the foul water of the house flows; also the wells and cesspools; and to look to the stables, that their floors have the proper inclination and allow the fluids to run off from the dunghoops which are often suffered to accumulate.

Establishments—such as schools, nurseries, *maisons de santé*, and places inhabited by dog-keepers, pig-feeders, rabbit-dealers, pigeon-fanciers, who seldom remove the offal; also the dwellings of rag-men, graziers, stable-keepers, bathmen, tanners, gut manufacturers; and, in short, all workshops which become nuisances by bad smells and want of cleanliness—will have need to be examined with the greatest care.

The commissioners will also see that the public streets in their respective parishes are properly paved and in good order, well swept, with the channels running free and cleanly washed; that the reservoirs of the fountains are in good repair, and sufficiently numerous; that the places of public convenience are well kept, and as many as need be; and whether there should not be new *urinoirs* established in certain situations.

The reports of the parish commissioners are to be made to the commissioners of districts, which last are to communicate with the central commission, and also to give their personal attendance in visiting those places from which they have not received satisfactory reports. The district commissioners are also to call upon the principal shopkeepers and artisans, and to solicit their exertions among their class for the more perfect purifying of the city; to insist upon the necessity of neatness in their houses and dress, and of temperance, the want of which produces such aggravation in the progress of an epidemic.

The business of the central commission is to discuss and digest the reports received from the district commission-

ers; to form the grand point of re-union of every thing concerned in these works; and to act immediately in connexion with government.

Members of the central commission engaged in drawing up this document, MM. Marc, J. Pelletier, Girard, Darcet, and Lucien Delamoriere.

CLINICAL LECTURES,

Delivered in the Dispensary of the London University,

BY

DR. ANTHONY TODD THOMSON.

LECTURE IV.

November 4, 1831.

Acute Hydrocephalus—Epilepsy.

GENTLEMEN,—The principal object of this lecture is, to direct your attention to the very interesting and highly-instructive case of acute Hydrocephalus, which was admitted on the 27th of last month, and which has terminated fatally—the too frequent result of cases of this formidable disease. As the little patient was necessarily confined to bed, and visited at home, a few of you only have had an opportunity of observing the progress of the malady; I will therefore enter a little more minutely into the history of the case than would be otherwise necessary.

George Harker, three and a half years of age, a fine intelligent boy, with light hair and blue eyes, was stated to be too ill to be brought to the Dispensary; he was, therefore, visited at his father's house. On inquiring into the history of the case, we were informed that, a year and a half ago, this child fell down an area, and struck the back part of his head with violence; he lay for two hours in a state of insensibility, with the eyes fixed. Since the occurrence of that accident he has been less playful than children of his age usually are; occasionally subject to attacks of dizziness: and, more than once, has suddenly fallen down. Six weeks since, when in the country, he caught a severe cold, was brought to town, and soon afterwards placed under the care of a medical gentleman, who lanced the gums under the impression that his complaints arose from dentition. On Friday, the 21st of October, he was seized with a violent pain of the head, which continued without intermission. The cough and difficulty of respiration, which were brought on by the cold, still remained, but only in a slight degree, having diminished from the time that the pain of the head came on. The bowels were relaxed, and the stools dark-green and offensive. Such was the account given by the mother.

At the time of taking the report the boy was lying on his back, the head a little inclined to one side, and the eyes closed: he expressed great intolerance of light. His mother told us that he cried for many hours together, sometimes uttering a loud and prolonged scream. He was very restless, especially at night, rolling his head on the pillow, and sometimes jumping up in bed. He was perfectly sensible, recognizing every one of his family; and put out his tongue when ordered to do so. There were frequent flushings of the cheeks, followed by dampness of the skin. The pulse was 116, full and soft; the skin was dry; the temperature moderate; the tongue little furred; the urine scanty, high coloured, and offensive to the smell. He refused food. On examining the head, it appeared larger than in children of a similar age, measuring $21\frac{1}{2}$ inches round, and 12 inches across the head, from ear to ear, in the direction of the coronal suture. Both parents are healthy, and not subject to complaints of the head. Two other of their children, however, died with symptoms closely resembling those of this boy; but neither of them had met with any accident. Ten Leeches were ordered to be applied behind the ears; and a powder, consisting of six grains of Calomel and eight of Jalap, was directed to be taken after the bleeding, and the head to be kept moist with a cold evaporating lotion.

On the second visit we found that four Leeches only had been applied; but the mother assured us that much blood had flowed after they dropped off. The same degree of restlessness, the rolling of the head on the pillow, and the screaming, continued; the pulse was 120, thin, and hard; and the stools had assumed the slimy, glazed appearance, which is so pathognomonic of acute Hydrocephalus. The pupils were not dilated; the tongue was still but little furred, and moist. Four grains of Calomel and three of Colchicum, were ordered to be taken every eight hours, and two table spoonfuls of a solution of six grains of Tartar-emetic in six fluid ounces of distilled water.

On the 1st of November the pupils were much dilated; he squinted, and complained of not seeing distinctly; there was some degree of delirium, and the pupils were occasionally turned upwards. The stools had lost their green colour and glazed appearance, and were pale and pasty; the tongue had become more furred, but was still moist; and this, you will find, is frequently the case when the brain is affected. The same plan of treatment was continued; and, as the head was hot, the application of the lotion strenuously enjoined. On the afternoon of this day convulsions supervened, and continued with slight remissions until ten o'clock on the following morning. The pulse was 148, and bounding; the pupils were still

sensible to light, but the patient appeared incapable of recognizing any one. At noon (November the 2d), the whole face was suffused with a deep scarlet blush; the eyes were protruded, the pupils much dilated, and the teeth fixed as in trismus, whilst the breathing was stertorous. The thumbs were thrown across the palms of the hands, and the two first joints of all the fingers rigidly bent inwards; the pulse was hard, bounding, and 150; the temperature high; and there was an evident tendency to opisthotonos. He had passed scarcely any urine since yesterday, and only one stool, which was dark-green and pasty, but not glazed. The head was very hot, although the lotion had been sedulously applied. The temporal artery was ordered to be opened, but, before five ounces of blood flowed, a state of collapse came on, which seemed to indicate a rapid fatal termination of the case; nevertheless the trismus did not yield. The breathing, however, lost the apoplectic character, but he became torpid, and continued so until he died. Enemas, composed of small quantities of White Wine Whey and four drops of Tincture of Opium, were directed to be administered every hour; and a large blister was applied to the nape of the neck. In seven hours afterwards he died.

Post-mortem Examination of the Body.—On laying bare the cranium, the sutures appeared more than usually consolidated in so young a child; and the adhesion between the dura mater and the bone was so great, that the skull cap was with much difficulty raised. The vessels on the surface of the brain were greatly congested; as were those also running through its substance; the medullary part displaying an infinite number of large bloody points. The whole surface of the brain was bathed with serum, and about two ounces of fluid were collected in the base of the cranium, passing down into the cavity of the spinal column. The appearances of inflammation were most obvious on the medulla oblongata, and in the sheath of the spinal marrow, particularly in the pia mater, which was beautifully injected. The quantity of fluid in the ventricles was comparatively small. The substance of the cerebellum was healthy. On opening the abdomen, the liver was found in a diseased state, studded with dark patches, which penetrated the substance of the viscus; several small tubercles, not larger than millet-seeds, were also observed in it. The spleen and the pancreas were healthy; but the mesenteric glands were enlarged, and some of them contained suppurating tubercles. The rest of the abdominal viscera were in a natural state.

Few cases, gentlemen, will come before you more fraught with important matter for remark, both in a theoretical and

practical point of view, than that the report of which I have just concluded. In tracing the origin of the disease, we should be tempted to refer it to the accident which occurred to the child eighteen months ago; but I am of opinion that that concussion impressed upon the brain a predisposition to take an inflammatory action, rather than that the inflammatory state of the meninges then commenced. It is true that the child displayed less sprightliness than usual in young children after the accident, but it is pretty evident that it was not until after he caught cold, six weeks ago, that the inflammatory action was set up; and there seems to have been a translation of diseased action from the lungs to the head, as the cough abated when the head became affected. How far the state of the brain, induced by a severe blow on the head, resembles that which may be denominated *hydrocephalic*, and which seems hereditary in some families, it is difficult to determine; but that such a state exists there can be no doubt, and there is as much propriety in talking of a *Hydrocephalic* as a *Scrofulous*, or any other diathesis: the constitutional disposition to many diseases is obvious, long before the habit is actually under the influence of the disease to which the diathesis is supposed to contribute. In this state of the brain, however it may be brought on, a diseased condition of the liver, or some other of the abdominal viscera, not unfrequently disposes the meningeal vessels to take on that action which terminates in effusion of serum, either upon the surface of the brain or into its ventricles. In our little patient's case, the primary diseased action was evidently in the lungs.

The knowledge of the fact, that, in families in which the hydrocephalic diathesis prevails, a transference of diseased action from any part of the body to the head is always likely to occur, points out the importance of early attention to even the slightest inflammatory attacks in such individuals; and more especially when the abdominal viscera are affected. In such a case as that now under consideration, I am of opinion that much security may be reasonably anticipated from establishing an issue, so as to divert the determination of blood to the head, and from constant attention to the bowels. In the present case, both the liver and the mesenteric glands were diseased; but it is probable that these were consequent on the state of the head, arising from the fall: and daily experience will teach you, gentlemen, that, in cases of cerebral derangement, conjoined, as they almost always are, with disease of the hepatic and chylotropic organs, nothing is so difficult as to determine whether the brain or the abdominal viscera be the primary seat of disease. The dizziness and falling down, which oc-

curred before our little patient caught the cold which proved the exciting cause of this affection of the brain, indicates a state of the organ similar to that which sometimes precedes attacks of Epilepsy; and if the life of the patient had been spared, he probably would have suffered from that disease.

The next observation to which I have to direct your attention, is the position of the patient on our first visit. He was lying on his back, with his eyes closed, to shade them from the painful stimulus of light. This affords me another opportunity of making a few remarks on the physiognomy of disease. When the brain is affected, the power of volition over the muscles is much diminished, sometimes wholly suspended; consequently, the position on the side, which is natural to us during rest, in a healthy state of the body, cannot be maintained, and the patient turns on his back. By observing this position, therefore, when it is attended with screaming, rolling the head on the pillow, and jumping up in bed, you may always form a pretty accurate idea of the state of the brain. These symptoms, however, mark a high degree of irritation rather than one of acute inflammation; but if the means taken to obviate this condition prove insufficient, the acute inflammatory action is rapidly set up, and runs its course to a fatal termination. It is true that the previous symptoms often so closely resemble those connected with Worms, or with Dentition, that the diagnosis becomes extremely difficult; but when we see the patient always lying on his back, and rolling the head on the pillow, we can scarcely be mistaken in pronouncing the disease to be *Acute Hydrocephalus*. In employing this name, gentlemen, I do it merely in conformity to established custom, for the *Hydrocephalus*, or *Dropsy in the Brain*, is certainly not the disease, but the consequence of the disease.

The thumbs thrown across the palm of the hands, and the clonic spasm of the flexor muscles of the two first phalanges of the fingers, with the accompanying trismus, indicate a high state of cerebral excitement, particularly on the base of the brain, involving the origin of the motor nerves within the cranium; and this the post-mortem dissection demonstrated to be the case, in a very striking manner. The crossing of the thumbs is not an unfrequent symptom of visceral irritation affecting the brain and medulla oblongata, in severe cases of dentition, and occasionally in irritation from worms: in these cases, the spasm is generally resolved by correcting the condition of the abdominal viscera by active purgatives, so as to make some impression on the brain; but when purging fails, bloodletting, followed by calomel and opium, must be resorted to. Trismus is a very uncommon termination of *Acute Hydrocephalus*, and can only be accounted for by the extension of the inflam-

mation of the pia mater to the medulla spinalis; for, in this case, there was nothing in the state of the abdominal viscera to which it could be referred. Late investigations, particularly those of the continental pathologists, have also discovered an increased vascularity of the spine in all cases of tetanus; indeed, when we consider that, besides the fixation of the jaws, the diaphragm, and abdominal muscles, the trapezius and the serratus magnus auticus are thrown into spasmodic contraction, we can only trace these effects to inflammation affecting the origins of the par vagum, the spinal accessory nerve, the phrenic and external respiratory nerves, or to those nerves affected by some other powerful irritating cause. That the former is the most probable cause, may be inferred from the permanent or clonic nature of the spasm.

The turning up of the pupils has been commonly regarded as indicating the effusion of fluid within the cranium; and, as it always appears towards the close of this formidable disease, the vulgar say "that children, with water in the head, are looking to their final home." It is said, that vulgar sayings are generally founded in fact, and this is true as far as this turning up of the eyes is the prognostic of great debility: but it is only when it occurs in our waking hours that it is so, for in sleep it is always present; and, therefore, we may all be said to be looking towards our final homes during sleep. You will read in Dr. Good's *Study of Medicine*, and other medical writings, that both the turning up of the pupil and strabismus is the result of spasmodic action, but the discoveries of Sir Charles Bell have demonstrated that this is an erroneous opinion. The turning-up of the pupil is merely an indication of great debility extended to the voluntary muscles of the eye, leaving the obliqui to act with relatively greater power, and it is by their operation that the pupil rolls upwards. The same thing, as I have already said, occurs in sleep, but it is not observed, owing to the eyelids being closed. When any circumstance occurs, however, to prevent the eyelids from closing, then it becomes visible. This is well described in a letter from Mr. Jackson, of Sheffield, which Sir Charles Bell has published in his admirable work on the *Nervous System*. The patient, owing to partial paralysis of the face, could close the lids of one eye only in sleep, whilst the other remained uncovered. "The right is closed," says Mr. Jackson, "and the upper eyelid on the left side remains as in the state of ordinary vision, whilst the inferior margin only of the cornea is visible; thus simulating the appearance on the paralytic side of a person in the act of dying." No feature, nevertheless, is so indicative of the state of the brain as the eye. In the early or inflammatory stage of *Acute*

Hydrocephalus, they are generally suffused, watery, and intolerant of light: when the state of oppression supervenes, the pupils become dilated, the eyelids are not closed even in sleep; strabismus, the rolling of the eyeball in its socket, and various contortions are observed. Sometimes in the commencement of the disease we find the pupil much contracted, with knitting of the eyebrows; but these symptoms rather indicate the existence of nervous irritation than inflammation in the membranes of the brain, although it is often mistaken for Arachnitis, into which it may decline, if not properly managed. It may be removed by a course of brisk purgatives, followed by the judicious and cautious administration of opium and light aromatics: if blood be abstracted, it should be in small quantity, and by means of leeches on the temples, or behind the ears.

The green, slimy, glazed looking stools, which are so characteristic of this disease as to be designated *Hydrocephalic*, demonstrate the powerful influence of the nervous energy on the secretion of the liver: instead of the ordinary secretion of the viscus, these green slimy stools are produced. It is of importance not to confound these stools with the dark green alvine discharges which usually follow the administration of Calomel in children; and which seem to depend on the mercurial stimulating the gall-ducts, and thus exciting the gall-bladder to pour out its contents, which, from having been pent up for some time, have become viscid or inspissated, and acquired a much darker green hue than recent hepatic bile. *Hydrocephalic* stools are distinguished from these by being very little acted upon by water, which is scarcely coloured or rendered turbid by them and by possessing little or no offensive odour. We know too little about the manner in which the liver, or any other gland, separates its secretion from the blood, to explain the nature of the change which produces *Hydrocephalic* stools; but we know that it is intimately connected with the state of the brain; and one fact of practical utility is worth a score of conjectural theories. If no change occur in this state of the alvine evacuations, a fatal prognosis may be pronounced; but the contrary does not always authorize us to venture on hazarding a favourable opinion; this is demonstrated in the case before us: the stools on the fourth day of the attack lost their *hydrocephalic* aspect, and became pale and pasty, whilst the disease was rapidly gaining ground. It was almost immediately after this change that the patient became insensible, and incapable of recognizing those about him; and it might be expected, that, as the fluid was poured out within the cranium and the inflammatory action was partly suspended, the function of the liver would become more

natural and, consequently, the bile reassume an appearance more consonant with its usual state.

The frequent fatal issue of attacks of acute *Hydrocephalus* has led to a too general opinion, that it is an incurable disease; and has, unfortunately, paralyzed those efforts that would otherwise have been exerted to trace and avert the causes of the evil. Let me warn you, gentlemen, against entertaining such opinions: every disease, which has a tendency to destroy a vital organ, becomes an incurable disease in the hands of the ignorant and the negligent; but *Hydrocephalus*, even in its advanced stage, after strabismus, blindness, and convulsions have taken place, as long as the pulse remains moderately steady, and the breathing continues natural, must not be contemplated in inactivity, as if the fatal event were inevitable.

In regarding the disease as an inflammatory state of the cerebral vessels, excited by external injuries, or more frequently by diseased states of the abdominal viscera, sympathetically affecting the brain, peculiarly predisposed by hereditary organization or accidental causes to take on diseased action, we are led to consider two distinct kinds of treatment, according to the period of the disease at the time our advice is demanded: the one *prophylactic*, the other *curative*. It falls to the lot of the practitioner to put the former in practice only when he is aware of an hereditary predisposition to *Hydrocephalus*, existing in a family, which has that implicit confidence in his opinion that would insure attention to it, even when the reasons for following it are not very evident to common observers; in exercising the second, it frequently happens that the disease has gained too great an influence before his efforts to overcome it are commenced.

As a prophylactic measure in those families in which the *Hydrocephalic* diathesis is suspected, the closest attention should be bestowed on the state of the abdominal viscera. In the slightest deviation from the healthy state, the hypochondria should be examined; if any tenderness on pressure be felt, leeches should be immediately applied; and if the stools be unnatural, Calomel, and Tartar Emetic, or James's Powder, in conjunction with Jalap, or Scammony, should be administered. But you must also bear in mind that when intestinal irritation is great, drastic purgatives frequently tend to increase it; and, therefore, instead of Calomel, combined with Jalap or Scammony, you will find the *Hydrargyrum cum Creta*, with the powder of Colchicum, better adapted to subdue irritation and promote healthy secretion. I have found the most obvious advantage to result from a long-continued course of the Wine of Aloe combined with

Alkalies. If, however, notwithstanding the openstate of the bowels, headache, or any other symptoms of morbid excitement of the cerebrum, display themselves, then the employment of more active purgatives should be resorted to; but these ought not to stand in the way of local blood letting, for it is only by subduing vascular excitement in its earliest stage and correcting the derangement of the digestive organs, that we can expect to ward off the influence of those causes, which have called into activity the morbid tendency of the habit, and to aid the powers of the constitution in restoring its healthy functions.

After the attack has really commenced, the depletion should be more active, but nevertheless limited. In the case under consideration, the number of leeches applied was inadequate to the effect, and it is probable that the account of the quantity of blood lost was exaggerated. Although aware of this, yet I was hopeful that, by purging actively with Calomel and Colchicum, with the addition of Tartar emetic in doses sufficient, by its nauseating influence, to abate arterial action, I should be enabled to diminish the general morbid irritability of the nervous system, without depressing too much the powers of life. The low state of the habit previous to the attack rendered much depletion by blood-letting a doubtful measure; and having had many opportunities of witnessing the beneficial effects of active purging in Acute Hydrocephalus, the leeches were not ordered to be repeated. It may be thought that the nature of the purgative to be employed is of little consequence; Calomel, in combination with Colchicum and an antimonial, not only stimulates the torpid bowels, and, by acting on the orifices of the gall-ducts, empties the liver, but it also aids in altering the abdominal secretions and exciting the languid absorbents; consequently it ought always to be preferred. I recollect Dr. Denman having informed me that he had ordered Elaterium in one case; the effect of which was a violent diarrhœa that continued for several days, during which the symptoms of the disease disappeared, and the child recovered. My own experience, also, induces me to place more confidence in purging than in bloodletting in Hydrocephalus. When, however, the symptoms of Apoplexy, with stertorous breathing, and the scarlet, flushed state of the face supervened, no alternative remained but opening the temporal artery: but, could I have anticipated the sudden collapse which followed, I think I should not have ordered it.

Some benefit might have possibly resulted from the substitution of Croton oil for the lancet; and as the fixed state of the jaws prevented medicines from being exhibited by the mouth, its effects would have been obtained by applying it to the surface, in combination with Opium. As the collapse

immediately followed the arteriotomy, the only chance that then remained, to avert the fatal issue, was to arouse anew and to support the powers of the habit. I cannot, gentlemen, urge too strongly the necessity of making yourselves familiar with the distinction which exists between Coma and Exhaustion; and warning you, immediately on the appearance of the latter, to throw aside Calomel, Antimonials, and every other depressing agent, and to have immediate recourse to White Wine Whey, or Brandy and Water, Ammonia, and Opiates, in adequate doses, frequently repeated, until evident symptoms of re-action display themselves. These are readily recognized by the pulse, which will become less frequent and fuller; by the warmth of the extremities returning; and, with the colour of the cheeks, the restoration of the natural expression of the countenance. As soon as this takes place, the howe's should be regulated by gentle aperients, such as Rhubarb and Magnesia, and the stimulants gradually exchanged for light nutritive diet and appropriate tonics. Were it necessary, I could detail to you several cases, in which I have snatched children, as it were, from the very jaws of death, by exchanging the depleting for the cordial plan of treatment, under which every symptom of threatened effusion has vanished, and the smile of returning health gradually returned to a countenance, which not twenty-four hours before displayed the *facies Hippocratica*—that fatal index of complete exhaustion, and, frequently, too certain harbinger of final dissolution.

It is unnecessary to make any comment on the appearances of the brain and the spinal marrow displayed in the examination of the body; they were such as satisfactorily to account for the symptoms that characterized the disease, and to add another proof, were any wanting, of the importance of morbid dissections.

Epilepsy.

I have no doubt, gentlemen, that you have observed, with satisfaction, the success of the plan of treatment adopted in the case of Leni. He has had no fit since the 27th of last month; but, nevertheless, although the headache has completely left him, yet he still complains of dizziness, and there is a constant winking of the eyes, with suffusion of these organs, and an expression of great anxiety. The pulse is 72, small, and irregular, and the tongue furred. The bowels are open, and the urine has lost its high colour. He has been ordered to continue the use of his pills, and mixture, with the addition of ℞xiv. of the Arsenical solution. I shall say nothing regarding the reasons for prescribing this tonic, until we shall have seen something of its effects.

REPORTS OF CASES OCCURRING
AT PUBLIC INSTITUTIONS.

GENERAL DISPENSARY.

Stricture of several years standing, Extravasation and Death—with Clinical Remarks.

JAMES FYNLAISON, aged 50, residing at No. 112, Aldersgate-street, was seized with shiverings, which came on once in twenty-four hours, and were so severe as to compel him to apply at the General Dispensary. The shiverings were speedily removed by the use of quinine; but Mr. Coulson was requested to see him for a difficulty which he had in passing his water. The patient said, that for twelve years past the size of the stream of urine had been diminishing, and that he had experienced at times great pain in passing his urine, and felt frequent desire to make it. These symptoms had of late very much increased. At this time he could scarcely pass any water, and what came away was passed in drops; there was great pain and a sense of scalding in the urethra, and on examination a swelling was found in the perineum. There was also great constitutional disturbance. It was very clear that some portion of the urethra was in a very diseased condition, and from the pain and scalding in the part, and swelling in the perineum, Mr. C. apprehended that ulceration of the urethra, and extravasation into the perineum, had commenced. A middle-sized catheter was introduced, without the least difficulty, as far as the membranous part of the urethra; but here a firm obstruction was met, and the instrument was instantly withdrawn. A small-sized catheter was tried, and with very little difficulty introduced into the bladder: about half a pint of dark-coloured fluid came away, and the patient felt much relieved. Mr. Coulson wished to make an incision into the perineum, but the patient would not consent. A gum elastic catheter was kept in the bladder; warm fomentations were applied to the part; an opiate was given immediately, and some aperient medicines ordered in the morning.

The patient had continued easy until the middle of the night, since which the pain had returned; the swelling had extended to the scrotum, and the prepuce was also œdematous. The necessity of giving relief by an operation was again strongly urged upon the patient and his friends, but the proposition was met by a decided negative. As the bowels had not been opened, a clyster was given; the pulse was small and quick, (120); and the countenance pale and anxious. The extravasation extended during the course of the day to the lower part of the abdomen, and on the penis there were vesicles filled with black fluid; the penis itself was semi-erect; the pulse 140, and very small; hiccup; now free from pain. In the evening he died.

The body was examined within 24 hours after death. The whole cellular tissue of the perineum, scrotum, penis, and lower part of the abdomen, were loaded with a dark-coloured fluid, having a strong urinary smell; the urethra was sound in every part except at the membranous portion, which was completely destroyed by ulceration, and the opening communicated with a cavity in the perineum of sufficient size to hold an egg; the prostate was enlarged, and the bladder inflamed.

Nov. 4th.—To-day, Mr. Coulson made the following clinical observations on the above case:—Gentlemen, this case of extravasation of urine with stricture, which occurred some time ago in this institution, shows the rapidity with which the mischief extends, and even death ensues, unless the most prompt and efficient measures be resorted to. The giving relief to the extravasated urine by free incision might have afforded the patient a chance of recovery, and ought in no case whatever to be neglected. Extravasation of urine may occur in consequence of pre-existing mischief in the urethra, (and is then frequently, though not always, preceded by retention,) or in consequence of violence, either external, as a blow, fall, &c., or internal, as the too forcible introduction of instruments. The symptoms, however, of the disease from either cause are pretty much alike: there is pain and a sense of scalding in the urethra, increased by any attempt at making water, swelling and tenderness of the perineum, which, in severe cases, generally extends to the scrotum, prepuce, and lower part of the abdomen, and the skin over the part where the urine has extravasated ultimately becomes gangrenous. When only a very small quantity of urine has escaped, a hard circumscribed swelling occurs, which terminates in an urinary abscess; the constitutional symptoms are very severe; fever of a typhoid character generally supervenes; and if the urine has not been evacuated by free incision into the part, the patient rapidly sinks: if, on the contrary, this plan of treatment has been adopted, the chances of recovery are much increased. The course which the urine takes is a point worthy of your attention, and depends on the attachment of the perineal fascia. The urine seldom makes its way down the inside of the thighs, or in the neighbourhood of the anus—a direction which, from the position of the body, you might naturally expect the urine to take. The urine, however, makes its way upwards, where the perineal fascia is loose, or has no fixed attachments, being there continuous with the fascia covering the anterior parietes of the abdomen. Laterally this fascia is connected to the rami of the ischia and pubes, and posteriorly it dips behind the transverse perineal muscles, and becomes connected with the anterior layer of

the triangular, or, as it is sometimes called, Camper's, ligament. Thus you will see that, unless the fascia is destroyed by ulceration or external violence, the urine cannot escape in these two latter directions. Sometimes the urine makes its way into the cells of the corpus spongiosum, and then the penis attains a large size, and in general becomes gangrenous; the penis also in these cases is in a state of erection. Mr. Brodie, in his valuable lectures on diseases of the urinary organs, (*vid.* Medical Gazette, vol. i. page 7,) says, that "a black spot may be sometimes seen on the glans of the penis; it is a most fatal sign, for I never knew one to recover in whom it appeared; it indicates that the urine has been effused into the cells of the corpus spongiosum." The urethra also gives way sometimes more anteriorly about an inch or so from the external orifice; in this case the prepuce will be most œdematous. I will now show you a curious case of this kind, in a man fifty-three years of age, who is at present under my care, and whose urethra has given way in this part. You perceive that when he is making water the anterior extremity of the penis, particularly the under surface, swells to a great size; the circumference of this part is seven inches. When he has emptied his bladder, he then empties this pouch, or second bladder, if I may so term it, with his fingers; it gives him little or no inconvenience.

The treatment in cases of extravasation of urine consists, first, in introducing a catheter down to the stricture, or, if you can, into the bladder—then place your patient in the same position as if you are going to operate for stone, and make a free incision in the perineum down to the ruptured portion of the urethra. If you have succeeded previously in getting a catheter into the bladder, you have nothing to do, when you have completed the incision, but to let the instrument remain: if, on the other hand, you have only succeeded in getting an instrument down to the ruptured portion, you must then, taking the point of the instrument in the urethra for your guide, endeavour, from the external wound, to pass a gum catheter into the bladder, and keep it there two or three days: if you cannot get a catheter into the bladder from the external wound, you will not have much to apprehend, as the urine will make its escape, if there be a free external opening: also make free incisions wherever the urine is extravasated. If the urethra is ruptured just behind the scrotum, this part attains a great size; and in this case you must make a very deep incision, guided by the middle line of the scrotum down to the ruptured part. I attended a case, not very long ago, with Mr. Lawrence, where the urethra had given way in this situation; we were obliged to make a free division of the parts in the manner in which I have now men-

tioned; the patient, however, died. Locally, apply warm fomentations and poultices, to promote the coming away of the sloughs, and when they have come away, apply some mild ointment to the wounds; internally, you must give some saline medicines till the sloughs have come away, and opiates, if at bed-time, and afterwards support your patients' strength with tonics, wine, and strengthening diet.

On examination after death, we in general find ulceration of the urethra to a considerable extent, the cellular tissue of the perineum, scrotum, and lower part of the abdomen loaded with urine, or in a state of gangrene. If there has been stricture of long standing, the prostate, bladder, and sometimes the kidneys, will be found diseased. Extravasation of urine from the urethra, as I said before, is frequently preceded by retention, or some such marked symptoms of disease in the canal, as to lead the practitioner, at a very early stage of the complaint, to detect its nature, and to adopt at once the proper means of relief: this, however, does not invariably happen. A case of extravasation came under my care in this institution, in 1823, where there had been but little previous disease, and at the same time no such marked symptoms as to lead me to detect the complaint. The case had been entered under the physician, but I was requested to see the patient for a pain and a scalding in the perineum. I at first suspected that there might be extravasation, and I asked him to make water, which he did in my presence, in a very good stream: at the time of making water, however, the pain was increased; he assured me also that he had never any difficulty in voiding his urine. I then thought nothing more of extravasation, but treated the complaint with the usual antiphlogistic means, as leeches to the part, and warm fomentations. The pain was followed by redness of the lower part of the abdomen, but there never was much swelling. The patient, however, rapidly sunk, and the post-mortem examination disclosed the real cause of the mischief.

There was a great deal of urine lodged in the cellular tissue of the perineum and lower part of the abdomen. There was no extensive ulceration of the urethra; the urine had escaped from three or four minute openings (of a size sufficient to admit a small silver probe) in the membranous portion of the urethra. This part of the urethra was also narrower than natural. I thought that it would be instructive to you to mention this case, for it made a deep impression on my own mind, the man's life having been lost from the nature of the complaint not being understood. I would advise you never to conceal an error in practice; if the only effect of concealment were to deprive our professional brethren of an ample source of in-

struction (for errors will occur to all), this of itself ought to form a sufficient inducement for us not to practise it. But this is not all—by keeping secret our errors in practice, we run the risk of bringing ourselves into a state to commit them without remorse, by deadening those moral feelings which the commission of errors in practice ought to excite in every honourable mind, and which, if properly cherished, form at the same time the strongest stimulus to avoid them.

THE COURIER *versus* THE MEDICAL GAZETTE.

THE Courier has thought fit to allude to the observations contained in our last number on the opinions of Dr. James Johnson: the protocols from Suffolk-Street have been interrupted, but another writer has adopted the same sentiments and the same language; and the Editorial writers have again put forth their own most dangerous doctrines on the subject of Cholera, which they assert not to be contagious, “as the Board of Health pretend.” It is of importance to the public that all points of this nature should be placed in their true light, that the extent to which those, who assume the guidance of public opinion, are entitled to confidence, may be at once determined, and on this account we feel called upon to make the observations which follow.

It is a mere mockery to urge persons to the observance of the quarantine, and in the same breath to ridicule the authority by whose advice such precaution is adopted, and to concur in the sentiments, and praise to the very echo, the reasoning of one who holds (or at least held) the disease to be non-contagious, and the danger to be imaginary: this, we say, is contradictory and inconsistent, yet it falls short of the plenitude of absurdity which some recent writers have displayed.

Thus the Editor of the Courier, about a fortnight ago, in commenting on certain letters published in his paper, says, “We insert to-day a letter with which we have been favoured from Dr. James

Johnson, one of the King’s physicians, on the subject of cholera. It is with great satisfaction that we lay before our readers the opinions of a gentleman so competent to the task which he has undertaken.” What, then, were the opinions to which the Editor thus confidently directed attention? Why these—that the precautions against cholera were perfectly useless. The following are the doctor’s words. After ridiculing the idea of keeping out the disease by measures of this nature, and speaking in irony of having ships ranged bow and stern along the coast, he adds, “I will hold it (*i. e.* the quarantine) perfectly guiltless of neglect of duty, should the pestilence pass this boundary by day or by night, and effect a landing on our shores.” Again, said Dr. Johnson, in a former letter inserted in the same paper, “I have no hesitation in reiterating my opinion, that if cholera comes to these shores, it will come shorn of its fatality, and coercible to a degree that will make the terrorists ashamed of their ominous predictions and visionary speculations.” Here the *Courier* also takes up the subject, and congratulates their readers on the opportunity “of removing the alarm, caused by the notices inserted in the *Gazette*, at the instance of the Board of Health;” and he adds, “It is satisfactory to see that fully completely exposed by medical authority of real weight.” Again, says he, “every thing in reason and in fact seems to show, that it is not contagious.”—(*Courier*, Oct. 29.) Very well: here is the opinion of the writer distinctly enough expressed, whatever may be its value. What, then, will our readers think of the reasoning powers of this gentleman when we inform them that within a week afterwards he denounced in the strongest terms those who had been weak or culpable enough to act upon the doctrines he had taken so much pains to inculcate. He alludes to cholera as having been imported into Sunderland from

Hamburgh, and then, evidently not aware that the admission of this fact was fatal to the doctrine of non-contagion, he adds, "The crews of several vessels from that port (Hamburgh) are stated to have been suffered to land. * * * If it be true that such negligence on the part of the authorities really did take place, we know of no terms of reproach and censure sufficiently strong to bestow upon them. * * * Is it conceivable that they could have allowed the crews of vessels from Hamburgh to have had communication with the shore merely because they gave no external proof of sickness?"—(*Ibid*, Nov. 4). In taking leave of this sagacious personage, we are fain to apply to him his own words, because "we know no terms of reproach and censure sufficiently strong to bestow upon those" who presume to utter *ex cathedra* opinions on a subject of the very rudiments of which they thus shew themselves to be totally ignorant, and who use whatever influence they possess over the public in the inculcation of a doctrine which, according to their own shewing, is not more erroneous than it is pernicious.

They (says the Times of Thursday, most truly) have much to answer for who would throw a whole nation off its guard, and from stubborn adherence to a gratuitous dogma, persuade men from taking simple and easy (provided there be time) means of repelling or mitigating a pestilence to which so many human lives have already fallen victims.

PRECAUTIONS AGAINST CHOLERA.

CHOLERA has been imported into England by a vessel which left Hamburgh after the disease had broken out there, and which was suffered to come up the river at Sunderland. The first person affected was a "keelman" named Stroud, and the next in succession to whom it spread were members of his family. It is remarkable that Sunderland has for some time been looked upon with sus-

picion, in consequence of some doubts as to the strictness with which the quarantine was there carried into effect. The accounts received in town have hitherto been of the most unsatisfactory nature, being lamentably deficient in particulars. After this, however, each practitioner is to send a daily report to Dr. Daun. Our accounts on Thursday gave fifteen new cases, and ten deaths; all among the lower orders. The time for deliberation, however, is gone by, and that which imperatively demands active exertion, has arrived. The possibility of its importation, and the fact of its being infectious, are no longer matters of doubt with reasonable men; and it behoves the authorities of every town and village in the empire to make preparations for the unwelcome visitor. London, we understand, is to be divided into districts; houses are to be prepared for the reception of the sick; and medical men are to be appointed, who will devote their whole time to the fulfilment of the practical measures deemed requisite. These, of course, will not be composed of the present Board of Health, who have been a deliberative rather than an executive body; and we repeat, that now is the time for action. Whether the present Board will be continued we know not, but the new parts of the machinery will, we believe, be immediately put in operation. We understand that army surgeons, and others over whom the government have power, are every where to be put in requisition; and we would advise farther—that, inasmuch as the disease may be communicated by one who himself has it not or in other words, as medical men may carry it to their patients—so, as a general rule, those who are in frequent intercourse with persons labouring under cholera, ought not to visit others, or go into society—at all events, without changing their clothes and having recourse to copious ablution. We are convinced that, in other coun-

tries, the neglect of this precaution has contributed to the extension of the disease. We shall return to this subject next week: meantime we take leave to ask, what is the use of stopping the vessels at the Nore, while the mail is allowed to come up in two days?

The new Board consists of Colonel Rowan, of the police department, Sir W. Pym, Hon. Edward Stuart, Drs. Russel and Barry; the latter gentleman having just returned from the Continent.

— — — A FALSE ALARM.

A PERSON, walking in Regent-Street, had an epileptic attack, on Wednesday: he was taken into a shop close by, at the instance of the Solicitor-General, who was passing at the moment, and Mr. Arnott, of New Burlington-Street, was sent for; by whom the nature of the attack was at once pointed out. Nevertheless, the circumstance got wind, and was magnified into a case of cholera; the government was informed of it, the Board of Health consulted, and the practitioner above-mentioned examined, all within an incredibly short period. This shews, at least, how much all are now on the *qui vive* on the subject.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Nov. 5th.

The Cholera.

IN our last number we gave some account of the proceedings of the Saturday evening previous, considering them as preliminary to a grand discussion which was to take place here on the Saturday evening ensuing; but in this we have been disappointed, and we regret to say that we feel it our duty to give no report this week. It would be far better, we should think, not to raise public expectation, nor appoint a night for discussing the subject of cholera at all, than for gentlemen to stand up unprepared with the grounds of their opinions, making vague assertions, and wasting the time of the meeting in desultory, inconclusive, and unprofitable chat. We except, of course, two or three of the members, who acquitted themselves on this occasion with their usual ability; but the debate,

on the whole—if debate it can be called—does not deserve to occupy any portion of our columns.

MEDICO-CHIRURGICAL SOCIETY.

THIS society commenced its meetings for the season on Tuesday last. Mr. Lawrence, President, in the Chair.

Want of space prevents us from noticing the proceedings this week. The prohibition of reporting has been removed.

NOTE FROM MR. COULSON TO MR. S. COOPER.

— — —
To the Editor of the London Medical Gazette.

SIR,

You will oblige me by inserting in your next number the following note to Mr. S. Cooper.

I am, Sir,
Your obedient servant,
WM. COULSON.

Dear Sir,—I take the earliest opportunity of acknowledging that I committed an error in my clinical lecture in stating that there were no observations in your *Surgical Dictionary* on the treatment of patients previous to the performance of the operation of lithotomy. The passage to which you have called my attention shews that my observations were too unqualified; but I still think that less of your valuable article on lithotomy is devoted to the particular subject I alluded to than its importance demands. Permit me to add, that nothing was farther from my intention than to make any observation calculated to convey an impression that I undervalue a work which I have always considered of high merit and great professional utility.—I remain, dear Sir,

Yours, very faithfully,
WILLIAM COULSON.

Charter-house Square,
Nov. 7, 1831.

S. Cooper, Esq.

NOTICES.

We cannot attend to the *reclamation* of a dissatisfied author: as he has not liked our first, perhaps he would be still less obliged to us for a second notice.

Mr. Lee will find that what he requests was done in No. 2.

In No. 3, we gave eight additional pages without any extra charge; but as we are this week compelled to add an entire sheet, to meet the great press of matter, the price is necessarily raised on this particular occasion.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES

ON

THE THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

LECTURE VII.

Nosological Arrangements, their inutility—Inflammation, sometimes a salutary process, frequently a dangerous disease—The Synptoms—Redness—Heat—Swelling—Pain.

I HAVE NOW, gentlemen, made the chief prefatory remarks which I deemed necessary before entering upon the consideration of particular diseases,—upon *special pathology*. I have confined myself to an exceedingly superficial view of the subject of *general pathology*, and to the explanation of a few of those terms which I shall most frequently have occasion to employ.

More minute remarks I shall reserve for various parts of the course: for example, when I come to speak of the causes of inflammation, I shall particularly dwell upon the *modus operandi* of various changes and degrees of temperature in producing disease; and when I come to speak of diseases supposed to be contagious, I shall enter upon the subject of contagion. I think it much better to treat these matters in this way, than to treat them in the abstract before entering upon particular diseases; by this means they will not only be better understood, but we shall be relieved from the tediousness of dwelling long at a time upon general subjects.

Now in the first instance I mentioned that one part of general nosology, or one part of general pathology, and indeed one branch of that part of pathology which is called nosology, is the *arrangement* of diseases—one branch, if I may so speak, of general nosology

is, *methodical nosology*. You will frequently hear the arrangement of diseases spoken of simply as nosology, but that is incorrect; the arrangement of diseases is not simply nosology, but *methodical nosology*—*nosologia methodica*.

It was long before an attempt to arrange diseases was made. I believe Felix Platerus was the first who struck out the idea of arranging diseases methodically; he was followed by Baglivi, an Italian physician, and Sydenham. However, it was a French physician who first actually arranged them systematically—Sauvages, who published his work in 1762. It was in that year that the first methodical nosology was presented to the world. After him came the celebrated Linnæus, who arranged every object in nature, and published his nosology at Sweden in 1763. Another physician, Vogel, published one in 1764. No sooner was the thought put in practice than every body went to work. The arrangement of Cullen was published in 1769; another was published by Dr. Macbride, and one by Sogar, at Vienna, in 1771, so short a time elapsed; then one by an author named Vitenus; one by Dr. Thomas Young, the celebrated English philosopher; and one still more recently by Dr. Good. There have been others, but these are the chief.

Now, however useful it may be to arrange diseases slightly, for the purpose of memory, and for the purpose of general views, I think it must be confessed that all these various *methodical nosologies* only perplex and encumber the mind. I studied the arrangement of Dr. Cullen formerly very minutely, and had great part of him at my fingers' ends, but I confess that my knowledge of it now is but of a very superficial kind, and that it was never of any use to me. The arrangements of Drs. Young and Good appear to me just as useless; and I would not, if I advise you honestly—and I hope I always shall do so—I would not advise you to plague yourselves about nosological arrangements. My own

experience tells me that it is a much greater plague to recollect the arrangement and all the hard words than to recollect the things for which the arrangement is made. I never found it of the slightest use, any more than the barbarous jargon of the *Propria quæ maribus* and *Quæ genus* of the Latin grammar.

On the inconsistencies and defects of these various arrangements, I will not dwell; for if you turn to any methodical nosology you will find them in sufficient abundance. You find exceptions made to the plan which the author has laid down in his arrangement, and you find the most gross absurdities. If you turn to Cullen's arrangement, for example, which is one of the best, you will find a large number of diseases daily occurring that have no place in his nosology. Such was his arrangement, that there was not only no place for many most important diseases, but he arranges itch and fracture together. In speaking thus of Dr. Cullen, allow me to say, that although I think little of his arrangement, there can be no doubt that it was far better than that of any of his predecessors; and I must be allowed to pay a tribute of respect to his memory, as one of the most sagacious and one of the best of men who ever joined himself to our profession. I should be very sorry to endeavour to captivate your minds by attempting to lower any one in your estimation; nothing can be more contemptible; and as it regards Dr. Cullen, nothing could be more unjust. You find in his work the utmost candour, and the soundest information; and although he indulged in hypotheses to which some Scotch physicians have been prone, yet independently of that his descriptions are elegant and simple, and you will find his definitions admirable. It is to be remembered that his work on the Practice of Medicine was not considered by him a perfect work, and he modestly called it "First Lines"—a mere outline; but such as they are you will find them, according to the information of that day, exceedingly useful; and it is on account of the excellency of the original work that I should perhaps prefer recommending to your study an edition of Cullen, with notes, to the work of any other individual. I think the advantage of having Cullen's work, with notes, although it should not contain more information, is, that you have the work itself of Dr. Cullen, which was not surpassed in his day, and has not since been surpassed, as far as respects the knowledge of that period. I think you cannot do better than study the edition by Dr. Gregory. There are many other excellent works, Dr. Gregory's, Dr. Macintosh's, Dr. Good's, any one of which is worth possessing, and would form a good basis for study, but I think altogether you will find Cullen's, with notes, the most profitable to you as students.

The most natural mode, in my opinion, in which we can attempt to arrange diseases in our mind, that which serves best for the purposes of recollection—for an arrangement is certainly useful—although I am not an advocate for a methodical one, so called—that which we most naturally fall into, is a two-fold arrangement; first, as to the nature of affections in general, whether they are inflammatory, structural, functional, mechanical, or parasitical; for whenever we see a case we immediately consider what is the kind of affection; and then, secondly, as to which is the part in which the affection occurs. This is the arrangement which I shall follow in these lectures. I shall first consider general diseases, such as affect every or most parts of the body—inflammation, scrofula, and various other organic diseases; and afterwards, having considered all the affections which may attack any part of the body, I shall proceed to consider those affections and all others, functional, mechanical, and parasitical, as they attack the body from the head downwards—a *capite ad culcem*. I think we all make two inquiries in considering any case; the one is the nature of the disease, and the other is the situation of it. This is the utmost assistance, I think, that the memory can have from arrangement, and this is the plan which is continually followed by practical writers. They write on particular diseases, whatever they may be—inflammation, cancer, &c., and of the whole diseases of particular organs, and sometimes of particular regions. You have one writer publishing a work especially on diseases of the urinary organs; another, entirely on diseases of the nervous system; another, entirely on diseases of the head; another, on diseases of the chest; and this course we naturally fall into. But, independently of that, we must make observations upon the general affections to which all parts of the body are liable. I am quite satisfied that this sort of arrangement—by which we consider general affections which may attack any one part of the body, and then consider the affection as seated in this or that part, will afford us all the assistance that arrangement can; and I hope you will never plague yourselves farther with methodical nosology.

Inflammation.

The first disease of which I will speak is the most general of all affections, one which attacks almost every part of the body, at least all vascular parts, and which is the most frequent of all diseases—*Inflammation*.

In the first place, this is the most general of all diseases; it will attack any part of the body that is vascular: in the second place, it is one of the most frequent affec-

tions. It is a disease which scarcely any person escapes; it is a disease which is seen every day. It occurs simply by itself, and it is the concomitant of a variety of other diseases. Many diseases are always inflammatory, though they are not simple inflammation—though there is something more than inflammation, yet inflammation is united with them; and many other diseases are frequently inflammatory, but not always. Besides, inflammation is continually occurring as a means of benefit to the body; it is not only a morbid process, but a process frequently set up by nature for the purpose of restoration, relief, and prevention. It is a disease, too, which proceeds from a vast number of causes—causes to the action of which we are continually exposed, whether we will or not.

Again, it is one of the most dangerous diseases when it affects certain parts, and any part when it proceeds to a certain extent; and it is always liable to be carried to this dangerous point. However slight an inflammation may be, it is always liable to become aggravated to a dangerous point, and it continually does actually attack the most important organs; and hence we may be justified in saying, that the consideration of inflammation is more important than that of any other affection of the body.

When it occurs not as a disease, but for the purpose of restoration—for the purpose of health, if I may so speak—the circulation of the part becomes increased, the quantity of blood becomes augmented, and more nourishment is afforded than before. If a part be destroyed, or divided, a degree of inflammation is set up, and fresh matters are deposited, so that the part is more or less renovated:—when a bone is fractured, a certain degree of inflammation occurs for the purpose of pouring forth a fluid, which afterwards becomes solid, and produces union.

In the next place, inflammation is frequently employed by nature to prevent the escape of matters into parts where violent inflammation would be produced; and is set up by nature to prevent its own occurrence in another spot. For instance, when an ulcer takes place in the stomach, or in the intestines, if it proceed unchecked, the contents of the stomach or the intestines are poured forth into the cavity of the peritoneum, and a violent inflammation is set up—an inflammation, in the greater number of cases, fatal. Nature, however, very frequently sets up a little inflammation outside the organ, exactly at the part corresponding to the ulceration within, by which means it is glued to the surrounding parts, fibrin is poured forth, the fibrin becomes vascular, the parts become still more firmly glued, and then the stomach or the intestines cannot ulcerate through into the peritoneum. Thus, a slight inflammation is set up in one spot to prevent an inflammation which would be fatal to the

patient. You will see the stomach sometimes attached to the peritoneum, and sometimes to the liver.

Then, again, nature employs inflammation frequently to give an exit to something which is injurious to the body. When a biliary calculus is impacted in the ducts, and is too large to escape, it sometimes happens that these ducts become attached by inflammation to the intestines. The inflammation, after it has excited adhesion, proceeds, perhaps, to ulceration, and when the latter occurrence takes place, the calculus escapes through the opening into the intestines. The inflammation, in the first place, is set up to prevent the communication which would afterwards take place into the peritoneum, so that the bile and the calculus shall not escape into it; and when all these parts are firmly glued, and the danger prevented, then, at the particular spot, inflammation goes on to ulceration, ulceration takes place into the intestines, and in that way an exit is given to the foreign body.

When a part of the body mortifies, whether through inflammation or not—yet when a part has become dead, and useless to the body, and injurious to it from its presence—then inflammation is employed for the purpose of separating it. At the boundary of the living part, inflammation is set up; a red line appears at the extremity of the healthy part, where the dead part begins, and that red line is a line of inflammation, which inflammation proceeds to ulceration. A furrow of ulceration takes place, and goes down till the part is ulcerated through, and the dead part falls off, having been separated by the ulceration of the living disease.

You see, therefore, that inflammation, although a most fatal disease in many cases—although conjoined with the most frequent and violent diseases—is sometimes a most salutary process;—sometimes employed by nature to produce an union of parts; sometimes to prevent the great mischief which arises from an effusion of fluids into parts where they ought not to go; and sometimes for the purpose of giving exit to foreign bodies, or separating dead parts from the living.

The general definition of inflammation is, “redness, swelling, heat, and pain;” that is to say, *morbid heat, morbid redness; swelling and pain* require no definition, but redness is common to some parts, and therefore we must understand morbid redness, and with respect to heat, morbid temperature. These are the four chief symptoms of inflammation—those which make the definition in general—in the words of Celsus, “*rubor et tumor, cum calore et dolore.*”

Redness.—These are the general constituents of inflammation, and if they do not all exist in all cases, still usually the greater number are present. Sometimes one

is absent, sometimes another, but the redness is never absent; the redness is certainly indispensable to our idea of inflammation, and it will sometimes exist without swelling, without heat, and without pain; without any of these individually being induced, without any two of them; and now and then the redness will exist alone without any of the three. Whether the state should then be called inflammation or not, may give rise to a difference of opinion. But frequently you have inflammation without any perceptible swelling; you must conceive the part to be a little increased in size, because there is more blood than natural, but without a sufficient enlargement to justify you in using the word swelling—without much increase of heat, and sometimes certainly without pain; and it is to be remembered that both the increase of temperature and redness, by which we understand a morbid degree of them, may arise from other circumstances than inflammation, as may also the swelling and pain.

Still, although redness is indispensable to inflammation, it is not every redness that we have a right to call inflammation; a certain degree of intensity is necessary to the idea of inflammation. How much cannot be specified; but, like sensations in general, it must be experienced to be learned. The requisite intensity will vary in different parts, according to their natural colour. A blush, or momentary rosiness, is not considered an inflammation, and every part is liable to this momentarily in health. As regards the cheeks, a degree of redness there would not be considered inflammation, which we should be fully justified in calling so if it affected other parts of the body. The most intense redness, that lasts only for a moment, we should not call inflammation. It must be in the cheeks—supposing the person has a natural colour—a very deep red, indeed, and more or less permanent, at least not a transient redness, though intense, for us to say that the cheeks are inflamed.

Again, the same degree of redness, the same intensity of it, would not be considered inflammation if alone, which would be considered so if there were also pain and morbid sensibility. If we saw in the cheeks a great redness, we should not hesitate to call it inflammation if we found the part were morbidly sensible, or if the patient complained of it smarting, and being painful independently of pressure. Although the redness might be less intense, and might not continue so long as alone to justify us in calling it inflammation, yet provided it be in a part which is not naturally red, like the cheeks—not liable like them to occasional flushing and rosiness, a much less degree of it, and a much shorter continuance, might give us the idea of inflammation. You see how many things are to be taken into the account. A know-

ledge of these things cannot be gained at once, and many circumstances must be called in to aid us in our judgment. When persons are speaking of redness in connexion with inflammation, instead of the mere expression *redness*, we ought to say *morbid*, or, perhaps, *preternatural* redness; because what is morbid redness in one part is not morbid redness in another—redness preternatural to the part affected.

Now redness is not only of various degrees of intensity in inflammation, but of various hues, being sometimes of a bright scarlet, sometimes rather purple, and of all intermediate shades. Besides varieties of hues in redness, the redness may be distinctly circumscribed in patches, or it may be insensibly lost in the natural colour of the surrounding parts, so that we cannot exactly say where it ends.

Heat.

We will now proceed to the consideration of the other symptoms, and first of *heat*. It is right to say, that for the same reason which makes one adopt the epithet preternatural or morbid, in regard to redness, we should likewise affix the same epithet to heat, because the body, in this country at least, and in most others, is hotter than the surrounding temperature, and therefore it is always hot. A preternatural heat, if not very great, is not of necessity inflammatory; and if it be very great and yet last but for a short time, even then it is not inflammatory. A certain intensity, and a certain duration, are necessary to constitute inflammation in the case of heat, as well as in the case of redness. The greatest intensity of heat, if transient, would not be considered inflammation. The burning heat upon the cheeks, the palms of the hands, and the soles of the feet, in hectic, is never considered inflammation, even though it is combined with preternatural redness. The most intense heat, and also the most continued, is not of necessity inflammation, unless it be united with a pretty permanent preternatural redness. The whole body may be of a burning heat for weeks, as hot as an inflamed part, and yet the skin is not said to be inflamed. The example of hectic shews that even a combination of heat, with intense redness alone, is not sufficient to give the idea of inflammation; for in these intense spots in hectic there is no pain, nor are the parts most affected tender on pressure. Besides that, I need not say that morbid temperature only comes on for a few hours in the day, and is a mere concomitant in hectic from another disease. In addition to this there is no swelling in this affection, and therefore we have still more reason for saying that it is not at all inflammatory.

In regard to heat, the temperature of the affected part appears much higher to the pa-

tient than it really is, which arises from the parts being in a state of morbid sensibility. In palsy it is not very uncommon, when there is no increase of temperature at all—no inflammation—for the patient to feel every thing hot, so that if he sit on any thing without his clothes, it strikes hot to him, or if he put his hand on any substance, whatever it may be, it appears as if it were heated. This is a peculiar state of the system, and not inflammation. There is in inflammation a general morbid sensibility of the part, and therefore the degree of heat which actually occurs produces greater effects than it would in any other part of the body. But although, from the morbid sensibility of the part, the increase of heat appears greater to the patient than it really is, there can be no doubt that in inflammation the temperature is raised. When the nostrils are inflamed, or the bronchial membrane, or the throat, the air that we expire is so heated in passing over the parts, that, as it comes out at the nostrils and lips, it is felt to be burning. If you apply your hand, which is in a state of perfect health, to the inflamed part, you feel that it is hotter than usual; and if you make use of a thermometer you ascertain the point to a nicety—you continually find the parts inflamed hotter by many degrees than other parts of the body; it is not uncommon for them to be 107° . John Hunter made experiments to shew that the temperature of inflamed parts was but little augmented—at least not higher, he said, nor even so high, as the circulation at the heart and the chest; that if the parts had naturally a lower temperature than the centre of circulation—as for instance the hands and the feet—and they became inflamed, their temperature never rose so high as the centre of circulation. The general temperature is said to be 98° , but it varies in different parts; and the farther you proceed from the heart the lower it becomes, because there is less circulation there, and the parts are more exposed to the temperature of the surrounding atmosphere. There is a great mass of substance at the trunk—there is less on the arms—still less at the extremities of the fingers, at the nose and ears, and there is more exposure.

Now John Hunter produced inflammation in the thorax, in the peritoneum, in the rectum, and in the vagina, very cruelly, and he found the heat but one degree and a half higher than before the inflammation, and he frequently found it exactly the same. He says that the temperature of the vagina, at the utmost, increased to $101\frac{1}{2}^{\circ}$, but he found the temperature of the tunica vaginalis only 92° in health, whereas, when inflammation was produced in it, it rose to $98\frac{1}{2}^{\circ}$, 98° being about the natural temperature of the body. It is to be remembered, however, that the scrotum is a part very much exposed to the surrounding air—a depending part, and therefore as much exposed to the sur-

rounding atmosphere as the hands, feet, ears, or nose; and he infers that the heat is never raised above the natural standard at the centre of circulation. If the natural temperature of the tunica vaginalis be 92° , certainly the increase to $98\frac{1}{2}^{\circ}$ is very considerable. He says that he once found the abdominal fluid to be as high as 104° , and he says that if inflammation attack any part with a temperature of 98° , the heat may proceed beyond that of a healthy person. Now, however correct these experiments may be, you have only in the case of erysipelas to take a thermometer, lay it upon the inflamed part and cover it up, and you will then see the temperature, although it be erysipelas of the leg, often raised to 104 , 105 , 106 , or 107 degrees.

That the temperature of the body may be increased very considerably under various circumstances, is shewn by the following facts: for example, Sir Everard Home observed the oviducts of a frog when about to spawn, and when a great local activity of circulation was going on, to be two degrees higher than the temperature of the heart. Now there was no inflammation here, but merely a great activity of circulation approaching to inflammation, such as occurs in the generative process, and the result was as I have stated; and if a mere natural process short of inflammation will raise the heat above that of the centre of circulation, you may well suppose what inflammation will do. Even in vegetables, when a certain process is going on with great activity, a very considerable increase of temperature takes place. When the *arum cordifolium* and the *arum maculatum* are about to burst, the temperature, by placing a considerable number around a thermometer, has been such as to raise it very considerably. Twelve were placed around a thermometer, and so high a degree of heat was developed in the physiological process of bursting, that the instrument was raised from a temperature of 70° to 143° . Even in fever, by placing the thermometer under the tongue, you find the temperature raised many degrees; and the same occurrence takes place in acute rheumatism. In one case of phlegmasia dolens, on placing the thermometer on the thigh, and covering it with the hand or bed-clothes, I found it rise to the same degree of heat that is frequently observed in fever and in acute rheumatism—namely, to 107 degrees. Indeed one gentleman says that, during labour, he has observed the temperature of the uterus, having introduced a thermometer into the vagina, to be 120 degrees. In the violence of the spasm in tetanus, the temperature is frequently as high as 107 degrees. There can be no doubt, therefore, that inflammation is frequently attended by a great increase of temperature: I have seen it myself in various inflammations of the surface. This, however, is not peculiar to inflamma-

tion; for, as I have stated, it occurs in fever and rheumatism, where the thermometer has not been applied to the rheumatic parts, but put under the tongue and in various parts of the body; and it has been observed likewise in many affections of the system.

But as an increased heat may exist without any inflammation, so inflammation—that is to say, redness and swelling, of an undoubted inflammatory character, as proved by the terminations—may exist without any preternatural heat. You will sometimes have inflammation, or what, certainly, I think we are justified in calling so,—that is to say, preternatural redness and swelling, going on to suppuration—without any increase of heat; and this state of the parts has been called *passive inflammation*. Some object to the term, and say it does not deserve the name of inflammation—it is mere congestion of blood; but it will go to suppuration, and therefore I think we are justified in calling it inflammation, although there is no increase of heat. It is right, however, to tell you that some actually object to calling such a state inflammation, and they limit the term “inflammation” to an active state in which there is pain and all those symptoms which I mentioned;—and, to avoid any quibbling, Andral calls any state in which there is a morbid collection of blood, *hyperemy*—excessive quantity of blood in a part: and when it is actively inflamed, *active hyperemy*; and when this passive state occurs, he terms it *passive hyperemy*. Thus he gets rid of the difficulty altogether, by no longer using the word inflammation, but using a word signifying congestion of blood, and applying one epithet or another to it.

Swelling.

If we consider the third of these symptoms—swelling—we shall find that it also may exist without any inflammation. Swelling, although frequently a symptom of inflammation (more frequently than not), may of course exist, just like an increase of temperature—just like an increase of redness—without inflammation. Any thing, almost, will produce a swelling. The mere displacement of a part, the dislocation of a bone, hernia, the mere effusion of hæmorrhage, or a mere collection of water or any morbid growths, whatever their character, or the presence of air within the body, will all produce swelling;—swelling may be produced by many causes besides inflammation. For a swelling to be considered inflammatory, it must be united with pain or a preternatural redness; and even then it may be chiefly dependent on other causes. For instance, in dislocation you may have inflammation of the ligaments and integuments, producing pain; but the swelling arises chiefly from the displaced bone. Again, it is to be remembered that inflammation may

sometimes exist without swelling, as is occasionally noticed in ophthalmia. In ophthalmia, the turgescence often gives rise to no perceptible swelling; sometimes there is a little swelling, but frequently this affection, and many superficial inflammations of the skin, are not attended by any swelling. Sometimes you will actually see a part inflamed in which there is scarcely any pain and no increase of temperature, but excessive redness and excessive swelling; the congestion is extreme, and gangrene, in such a case, is very likely to take place.

You therefore see that not only the symptoms will arise from various other causes than inflammation, but they are out of proportion frequently, when they do occur, to each other. Sometimes a little inflammation is attended by very violent pain, and sometimes a little inflammation, a little increase of heat, is attended by the most violent swelling. There is no necessary proportion between any of these symptoms.

Pain.

Then if you take the last of these marks of inflammation—pain, we shall find that it will arise from many other causes than inflammation. Pain will arise from a mere spasm; nothing is more painful, for example, than cramp in the legs. Pain arises frequently from scirrhus, or cancer: some call this “chronic inflammation,” but certainly there is something more than that. Pain, too, is frequently neuralgic; a violent affection of the nerves, in which no inflammation can be detected during life, and no effect of inflammation discovered after death. Pain continually arises from inflammation, but it continually arises also from the other sources just pointed out; and sometimes it is absent in inflammation. You will see a part violently red, violently swollen, without any pain at all; and nothing sometimes is worse than this, for the part may fall into gangrene.

Just as there may be varieties of redness and various hues of redness, so there may be varieties of pain. The pain is sometimes tense: if the part be one that will not stretch, then the pain is of a tense character, and the part feels as if it would burst. If it be inflammation inclined to suppurate, the pain is of a throbbing character. If it be inflammation of the skin, the pain is frequently of a smarting or of a tingling character. If it be inflammation of a mucous membrane, you frequently have it characterized by a burning and pricking pain. If it be inflammation of a serous membrane, a stabbing sensation will often be experienced, as though a knife were being plunged into the part. There are, therefore, great varieties of pain, just as there are a variety of hues of redness.

PESTILENTIAL CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

A PAPER having appeared in your last number from Dr. Stanley, on the treatment of cholera, I wish to state in the forthcoming number of your excellent work, that the remedies he mentions were previously recommended by me, in an article on the nature and treatment of this disease, published in the October number of the Foreign Quarterly Review. Indeed, an account of the means both of prevention and of treatment there detailed was sent, several months since, to the Russian Ambassador, with the view of having it transmitted to St. Petersburg; but I doubt if my intention was complied with, for my communication was returned shortly after; but whether a copy had been taken of it or not, I cannot say.

Without noticing the facts from which I have deduced the inference respecting the infectious property of this pestilence, I will merely state the conclusions at which I have arrived regarding its nature generally. Your able and conclusive leading article on the infectious nature of the malady, must, together with what has been adduced elsewhere, particularly in the Review alluded to above, have convinced those who are open to conviction of the truth of our doctrine. More is not required on this topic.

Its Nature.

1. The pestilential cholera is propagated by an animal miasm or effluvium, of a peculiar kind, emanating from the bodies of the affected; and this effluvium being inhaled with the air into the lungs, paralyses these organs, and acts as a poison on the class of nerves which supplies the respiratory, the assimilating, the circulating, and the secreting viscera, vitiating also the whole mass of blood, and thereby occasioning a specific disease, which, in its turn, gives rise to an effluvium similar to that in which itself originated, which also, in like manner, perpetuates its kind, under the favourable circumstances of predisposition, aerial vicissitudes, temperature, &c.; and thus a specific state of disease is propagated far and wide, as long as

predisposing, concurrent, and determining causes favour its perpetuation.

2. The morbid impression made by this effluvium, or poison, on the nerves of organic life, and most probably the effect of its introduction also into the current of the circulation, are of a sedative kind, rapidly destroying the vital energy of the former, and vitiating the latter, and thereby giving rise to the characteristic phenomena of the malady.

3. The impression of this effluvium on the organic class of nerves, and the vitiated state of the blood, may be viewed as the proximate cause, not only of the disturbance evinced by the respiratory, the secreting, the assimilating, and the circulating functions, but also of the morbid actions of the stomach and bowels, as well as of the muscular spasms, the sinking of all the vital and animal powers, of the shrunk and collapsed state of the surface of the body, of the black thick state of the blood, and of the rapid depression of the animal temperature.

4. The morbid state of the perspiration, and the peculiar appearance of the evacuations, proceed from the alteration produced in the condition of the blood; and it is chiefly through the medium of the cutaneous surface, and of the mucous membranes, assisted perhaps also by the other secreting viscera, that this morbid state of the blood is remedied, and its impurities removed, in those who recover; and that the morbid effluvium or poison, which propagates the disease, is formed on these surfaces and membranes during the elimination of the impurities generated in the circulation.

5. The consecutive symptoms of the disease, whether those chiefly depending upon the state of the nervous functions, or of the circulation within the brain, or proceeding from the condition of the abdominal viscera, arise partly from the shock received by the vital energy of the frame in the early stage of the disease, partly from the arrest of the natural secretions, and the unchanged and impure state of the blood; and partly from the congested condition of the large veins and important viscera.

6. That neither the causes which occasion this pestilence, nor the pathological states which constitute its various stages or grades of intensity, have any connexion with those of any of the forms of cholera—whether the common *bilious*

variety, or the more severe form usually denominated the *spasmodic*, the *mort de chien*, &c.; and that, therefore, this name should be discarded from all scientific descriptions of the present pestilence.

Such, sir, are some of the conclusions at which an attentive examination of what has been published respecting this disease, has enabled me to arrive. As to the particular denomination, which may be applied to it, I conceive that some one, pointing to its chief pathological states, and its prominent tendencies, ought to be preferred: the intense influence of its exciting cause upon all the respiratory actions and functions, as well as upon the actions of the heart and state of the pulse, and its marked tendency to propagate itself, and to terminate fatally, induce me to apply to it the name of *Asphyxia pestilenta*, or pestilential asphyxia; and I would venture to offer the following definition of it:—

NOSOLOGICALLY.—Great oppression and anxiety at the præcordia, with giddiness, faintness, and general depression of the vital energies of the frame; cold, clammy, purplish, and shrivelled state of the surface; cold and raw state of the expired air; ejection of the contents of the stomach and bowels, with general tremors, spasms, and distress; a sense of oppression, pain, and heat at the epigastrium, with rapid sinking of the pulse, and of the animal heat.

PATHOLOGICALLY.—Paralysis, more or less complete, of the lungs; arrest of the changes effected by respiration on the blood, and of all the natural secretions; the circulation of a dark and otherwise vitiated blood through the arteries, with congestion and stagnation of the fluid in the large veins, sinuses of the encephalon, and internal viscera; sudden depression and rapid sinking of the heart's action; at last, a black, glutinous condition of the blood, with stagnation of it in the large veins and cavities of the heart, followed by death.

The most important considerations connected with this subject, are such as respect the prevention of the disease: when it is fully developed, there is reason to believe that even the most energetic means of cure will entirely fail, in a large proportion of cases. The measures of prevention which I would

especially recommend for adoption, are the following:—The use of sulphate of quinine, with camphor, or the aromatic spices, in moderate doses, taken night and morning, whilst the disease is prevailing in the vicinity; regular living, with a regulated state of the stomach and bowels, by means of tonics combined with gentle aperients: a firm state of the mind, and absence of all apprehension of the disease.

During the occurrence of the malady in our vicinity, or in our families, these means are more particularly required:—A free ventilation of every apartment ought to be constantly attended to, in conjunction with fumigations, by means of aromatic substances kept slowly burning, or by the vapours of chloruret of lime. The attendants on the sick should especially attend to the measures now prescribed, and ought never to exert their attentions on the affected so near their persons as to inhale the effluvia emanating from them, without fortifying the vital energies in the way pointed out; and they should carefully avoid entering upon those duties with an empty stomach, or when fatigued. Besides burning warm aromatic substances and odoriferous gum resins in the apartments of the house in which any person may be affected, a saturated solution of camphor, in aromatic vinegar, or in the pyroligneous acid, should be occasionally sprinkled on the floors of the apartments. These means, with a thorough ventilation and a due attention to cleanliness, will not only, I am persuaded, counteract the influence of the effluvia proceeding from the affected, and ward off its action on even the predisposed, but will also prevent the clothes, bedding, or furniture of the apartments of the sick from becoming imbrued with it to such an extent as can communicate the malady. They are within the reach nearly of all; and, in the event of the extension of the pestilence to any considerable town or city, if care were taken to see them put in practice, under the direction of Medical Councils of Health, one of which should be formed in each district or quarter, much good would result from them.

Having been required, in the various fields of practice, to treat diseases sometimes as rapid in their progress and as fatal under the usual methods of treating them as the malady now the subject

of consideration, I conceive that it will not be considered presumptuous if I recommend a trial of those means which, from my having employed them beneficially in these diseases, I would myself be induced to employ in the one now so much dreaded. When the usual measures fail, others which have succeeded in similar states of morbid action, particularly when they cannot prove detrimental, should be resorted to; and I am not aware that the following means, particularly as respects the combination of them, have ever been employed in this disease—at least at the time when I transmitted them, with more detailed remarks, to the Russian ambassador, or subsequently sent them to the Foreign Quarterly Review.

As I conceive that the exciting cause of the disease makes its first morbid impression on the nerves of the lungs, the propriety of directing the means of prevention to that quarter, and treatment also, will appear obvious. The means which I have noticed for the former purpose have been directed accordingly; but the morbid actions constituting the malady are of that kind that cannot be removed by medication administered in that quarter further than in a subsidiary manner. If, therefore, I were called to a severe case of this disease, besides directing blood-letting, if the circumstances and symptoms of the case appeared to warrant it, I would recommend the patient to have a bolus consisting of from ten to fifteen grains of camphor, an equal number of grains of calomel, one or two grains of opium, and ten drops of any essential oil—as of cloves, mint, cajeput, &c. with a sufficient quantity of conserve of roses. This should be administered without any regard to the presence of vomiting. If this be retained, another may be given, and repeated in from one to two, three, or four hours, according to the urgency of the attack; but if rejected, it should be immediately repeated, until it at last remains. At the same time external heat should be applied, and frictions, with a liniment composed of two ounces each of liquid ammonia, of olive oil, and of camphor, with three ounces of spirits of turpentine, and a few drachms (from three to six) of hard soap and Cayenne pepper, to which one or two drachms of cajeput and lemon oils may be added, ought to be assidu-

ously employed. From two to four hours after the exhibition of the bolus, a draught, consisting of from two drachms to half an ounce of spirits of turpentine and the same quantity of olive oil, with a few drops of the above essential oils and forty grains of magnesia, should be taken in mint water; and if it be rejected from the stomach, another should be given, and repeated, if again rejected, in half an hour afterwards; if retained, not until from six to twelve hours, when another may be taken. I have seen cases where the most urgent vomiting existed, and yet the above remedies (although both the bolus and the draught were taken at the same time) allayed instead of aggravating this symptom.

In order to promote the influence of these means, a lavement, consisting of twenty grains of camphor, from half an ounce to an ounce and a half of spirits of turpentine, and an equal quantity of olive oil, in a suitable vehicle, should be administered, and repeated according to the circumstances of the case. Much will depend upon the succession in which these remedies should be given, the periods which should be allowed to elapse between their exhibition, on the doses, and the decision with which they may be prescribed. When the irritability of the stomach continues, and if the attack be severe, then flannels, wrung as dry as possible out of very hot water, and immediately soaked in oil of turpentine, ought to be instantly applied, as warm as possible, over the stomach and abdomen, and retained there, or renewed, until a decided effect is produced. This is the most powerful means I am acquainted with, and the most successful in procuring reaction and restoring the heat of the body. In aid of these means, and when reaction is either commencing or even expected, effervescing draughts, composed of the carbonate of ammonia, and the pyroligneous acetic acid, mint-water, and aromatics, either in the state of spirit or of essential oils, may be given from time to time. Having found the above treatment eminently successful in treating diseases of remarkable malignity and fatality—in rousing the energies of life, restoring the secretions, and removing internal congestions—more particularly in the treatment of puerperal and other fevers

of an adynamic or malignant character, I have been induced to recommend it in the present pestilence.

JAMES COPLAND, M.D.

Consulting Physician to Queen Charlotte's Lying-in Hospital, Senior Physician to the Royal Infirmary for Children, &c.

Bulstrode-Street, Nov. 12, 1831.

neglect of any precautionary measures, it would, indeed, be lamentable, as thousands might suffer the penalty of the bad judgment of a few*.

I am, sir,

Yours, &c.

CHOLERA—THE TOPAZE FRIGATE.

To the Editor of the London Medical Gazette.

SIR,

IN common with all my professional brethren, I feel deeply for the consequences of the invasion of the Cholera Morbus into this country; and likewise I feel deeply the awful responsibility to be incurred by those entrusted with the lives of their fellow-creatures. Under existing circumstances, therefore, the establishment of the truth, with regard to the contagious or non-contagious nature of this destructive malady, is of paramount importance; and to have it in my power to correct a misstatement on either side which might lead to erroneous conclusions, and not to do so, I should consider a dereliction of duty. It has been stated repeatedly that the Topaze frigate conveyed the cholera to the Mauritius, from Trincomalee, in the island of Ceylon; which has been denied in the newspapers, journals, and verbally at the Westminster Medical Society, on the 5th instant, by a gentleman whom the audience considered good authority, being informed by himself that he was in India at the time. This gentleman stated positively that cholera had existed at the Mauritius previous to the arrival of the Topaze; that this ship could not have conveyed the disease, for that in point of fact the cholera was not on board.

The subjoined extract from the journal of the surgeon of that ship, now an official document, written and lodged at a public office years before the present crisis was contemplated, will set this question at rest.

Part of the public have been prevailed upon to believe that the disease is not of a contagious or communicable nature. Should such an opinion, or reliance upon such opinions, lead to the

Extract from the Journal of Mr. James Foy, Surgeon of His Majesty's Ship Topaze.

As many of the sick as could be accommodated were sent to the Naval Hospital at Trincomalee, on the ship's arrival there on the 5th September, 1819; they amounted to twenty-six, leaving forty-six on board. Four of the cases of dysentery that were sent to the hospital relapsed there and died. Whilst in this harbour Robert Thomas, sail-maker, who had been employed working on board the hulk previous to his illness, and Charles Plato, a marine, who attended in the purser's steward's room, and was exposed in that situation to sudden vicissitudes of temperature—both died on board of cholera Indica, after a few hours illness; the former on the 16th, and the latter on the 20th September. Some others were attacked with this disease, but they recovered. David Pearce, seaman, a man formerly much employed in the hold, also died at this time, having had a relapse of dysentery. Permission could not be obtained from the commanding officer to inspect the body of the latter.

The ship being ordered to the Mauritius, all but one of the remaining sick belonging to her were embarked again from the hospital, under the impression that the change of climate would be beneficial to them, for but little essential improvement, if any, had taken place in a great number of them whilst on shore. The situation of the hospital is not considered favourable to recovery. The ship therefore sailed in this state from Trincomalee on the 9th of October, having fifty-seven on the sick list; and immediately after cholera Indica broke out, and attacked seventeen, four of whom fell its victims, viz. Wil-

* The official document was put into my hands by my friend, Sir Gilbert Blane, to whom it was furnished by Sir Wm. Burnett, the medical commissioner of the navy.

liam Smith and John Dixon, seamen, who had not completely recovered from dysentery; the latter was one of the men returned from the hospital, and who had been ill with hepatic and dysenteric symptoms ever since he was on shore watering at Singapore, three months before: James Cooper, seaman, an old man sent on board by the civil power, for smuggling, who was much depressed in mind, and had suffered from scurvy on the passage from Manilla: William Steward, seaman, lately entered from a merchant ship.

There died also on this passage to the Mauritius, Esau Sheldrake, ship's corporal, of acute hepatitis, and Charles Farr, marine, of dysentery; the latter had been received in a hopeless state from the hospital.

On the arrival of the ship at the Mauritius on the 29th October, all the sick that were confined to bed, in number thirty, fifteen of whom were of the number received from Trincomalee Hospital, were comfortably accommodated in the Military Hospital at Port Louis, under the care of the military medical officers. The remainder, with the convalescents, were placed in the quarters on Tonnelier Island, which were given up for their accommodation by the General commanding. Six of the men sent to the Military Hospital died there; viz. four of the sequelæ of cholera Indica, with which disease they had been seized on board; one of these four had brought on enteritis by inconsiderate exertion and exposure on board when convalescent; the other two were long standing cases of dysentery. The whole six were of the number received ill with dysentery from Trincomalee Hospital: of the sick who were placed on shore on Tonnelier Island, four died who had been long ill; viz. John Twaites (cook's mate), Philip Harvey, James Coffy, and Francis Lilly (seamen): all of them had recovered from dysentery and cholera Indica a short time before, but remained extremely debilitated, and had a return of dysenteric symptoms, under which they sunk.

Three weeks after the arrival of the ship at Port Louis, the cholera Indica made its appearance amongst the inhabitants, and continued to carry off in Port Louis from fifty to sixty persons daily, chiefly slaves. It appeared im-

mediately afterward in other quarters of the island with equal fury. It was suspected by the inhabitants that the disease had been introduced by His Majesty's ship *Topaze*; for, although the Medical Committee, composed both of English and French practitioners, had, in their public report, declared the disease not to be contagious, nor of foreign origin, yet some of the same French practitioners suffered the inhabitants still to entertain their suspicions, and even appeared to agree with them, notwithstanding their public declaration. The consternation was unbounded and nearly general. In consequence, remonstrances were made against the ship being taken into the Trou Fanfaron, the only place of safety for a ship in the then approaching hurricane months, and the wishes of the General commanding were acceded to, by taking the ship to the Seychelles Islands, where she remained during the hurricane season; but previous to the departure from Port Louis, six men were sent to the Military Hospital, being unfit to be carried to sea; three of them, severe cases of dysentery, died there; one of the latter was of the number received on board from Trincomalee Hospital ill of dysentery, and was afterwards seized with cholera Indica on board; he recovered from both of these, and became convalescent, but from irregularity in his diet relapsed. Dysentery still harassed the ship's company during her stay at the Mauritius; but no case of cholera occurred after her arrival there, although all the merchant ships in the harbour were losing men by this disease. The weather was warm and without rain; the thermometer ranged from 78° to 82°. The cases of dysentery were separated from the rest of the crew as soon as they appeared, by landing them on Tonnelier Island, under the care of Mr. Porteous, assistant surgeon of this ship, to whose ability and uncommon attention these unfortunate men were indebted for their recovery.

WARM AIR BATH.

To the Editor of the London Medical Gazette.

SIR,

I SHOULD feel obliged by your giving insertion to the following case, in which the "warm air bath" was used with decided benefit.

I am, sir,
Your obliged servant,
W. WOODMAN.

Exeter, Nov. 8, 1831.

On Monday morning, November 7th, I received an urgent message to see Elizabeth Sprague, aged 65, residing in a very confined part of the city. On my arrival I found her writhing with agony, and complaining of excruciating pain and icy coldness of the stomach. The surface of the body was quite cold, the countenance anxious, the pulse almost imperceptible. She informed me she had been in that state about half an hour, but had been complaining all night of some pain in the stomach, with cramps in the legs, and had not been well since Saturday; she had not vomited or been purged, and the cramp had now left the legs; tongue clean and moist.

I immediately gave her 30 drops of cajeput oil in a little warm water; in about five minutes she vomited what appeared to be her breakfast; she now felt relieved for a few minutes, but the pain soon returned with its former severity. A large mustard cataplasm was now applied to the stomach, and 20 drops more of the cajeput oil, given in warm brandy and water; she soon after felt rather less pain of the stomach, but the coldness of the surface, the pulse, and other symptoms of collapse remaining unabated, I was induced to use the warm air bath, and am happy to say with complete success, as, in about five minutes the surface of the body became warmer, and in about eight minutes more it was above the natural temperature, with the pulse full and throbbing, and attended by complete relief at the stomach. In the evening she felt quite comfortable, with a soft pulse and moist skin.

My intention in reporting the above case is to call the attention of the profession to its resemblance in some of the symptoms to cholera, and to the facility

with which, in the short space of thirteen minutes, re-action was completely established, the temperature of the body being raised above the natural standard, and the pulse, from being almost imperceptible, becoming full and throbbing. I should therefore earnestly recommend the different Boards of Health to provide a proper supply of the baths, in order that a fair trial may be made of their utility, should the cholera unfortunately appear among us. Its portability renders it applicable in every instance; and without the least fatigue to the patient we are enabled to surround his body with an atmosphere of warm dry air, which, acting as a stimulus to the whole surface, will tend to relieve internal congestion, and restore the cutaneous circulation to its natural state.

INHALATION IN CHOLERA.

To the Editor of the London Medical Gazette.

October 25, 1831.

SIR,

If you think the following hint likely to be of practical use, it is much at your service for insertion.

During the perusal of some papers inserted in your Gazette, particularly one by Dr. Barry in the 194th Number, in which he describes cholera to be most fatal in its first stage, and when accompanied by the following symptoms—"Sudden paralysis, and rapidly diminishing action of the heart, of the arteries, and of the organs of respiration, with stasis and thickening of the blood, the loss of the power to generate heat," &c., the following idea occurred to me, viz. that these symptoms might perhaps be relieved by the inhalation of the protoxide of nitrogen, or dephlogisticated nitrous air of Priestley. Most of the profession are aware of its exciting effects, and that those effects are immediate, and not followed by the depression usually produced by opium or spirits.

I remain, sir,
Yours sincerely,
M.

ABORTION.

To the Editor of the London Medical Gazette.

Lincoln, October 1831.

SIR,

SHOULD you think the following case of sufficient interest, I shall feel obliged by your giving it insertion in the Medical Gazette.

I am, sir,
Respectfully yours,
FREDERIC KENT.

— Lee, aged —, called upon me, in August, 1830, to request me to attend her in labour, which she expected would take place in November. She has had several children, and reckoned with great accuracy. Thought she quickened early in July. I was not sent for till the 13th of December, at which time she was not larger than a woman four months gone with child. She was complaining of violent pain in hips and loins, sickness, great debility, with loss of appetite and sleep. During the last two or three months her abdomen had been distended to the size of a woman at her full time, when the above symptoms were much increased, and accompanied with pain and difficulty in making water, great pain when having stools, and tenesmus. These symptoms were relieved by the discharge of two or three quarts of a brownish-yellow fluid, not in the least offensive, and generally having several pieces of thin membrane floating in it: occasionally the fluid was mixed with blood. On examination per vaginam, I found the neck of the uterus nearly its natural length—the uterus rather larger than a child's head. I now asked her very particularly about her pregnancy, and, from her account, I was satisfied she conceived about the latter end of February or beginning of March. I do not think it necessary to enter into a detail of the treatment. I tried, upon two occasions, to expel the contents of the uterus, by the *secale cornutum*, but with no good effect. She continued to have the occasional discharges of fluid till the 28th of January, 1831, when, after violent flooding, a placenta was expelled about the size of a child's head. In spite of all sorts of treatment she continued, from this time to June, to have repeated floodings, with discharges of fluid. At the latter

end of June she could not get out of bed; kept alive almost entirely by wine and quinine. In September the floodings had nearly ceased, and she was able to walk about the house.

October 20th.—She still has occasional discharges of fluid, but in less quantity, and is gradually gaining strength.

On laying aside the membrane attached to the placenta, the latter presented a surface covered with hydatids of a purplish colour, varying in size, from a pea to a small walnut; several loose folds of membrane, which appear to be remnants of the burst hydatids; a blighted ovum, rather larger than a horse-bean, attached by a funis near the middle of the placenta; eyes and extremities distinct. It was discharged, as nearly as can be calculated, eleven months after conception.

I consider the above case rather singular, as I believe hydatids, connected with the uterus, are always described as pedunculated; and, on referring to Baillie, Burns, and Blundell, I find nothing similar to the above.

OVARIAN DROPSY.

To the Editor of the London Medical Gazette.

SIR,

THE annexed case is at your service, if you think it worthy the notice of your valuable periodical.

I possess notes of a very interesting case of asphyxia, from hanging, successfully treated. I opened the larynx, and inflated the lungs with a common elastic gum catheter. Also three of lithotomy—respective ages, $2\frac{1}{2}$, 8, and 70, in which I used, with very great satisfaction, Frère Come's instrument, the *lithotome cachée*, so much condemned by some eminent surgeons. It possesses all the advantages of the knife, without that great defect—not being able to regulate the extent of the incision through the prostate.

Should you wish these, I will with much pleasure send them to you.

I am, sir, a subscriber,
and your obedient servant,
THOMAS FEREDAY.

Dudley, Oct. 31st, 1831.

Case of Ovarian Dropsy, complicated with Psoas Abscess and Pregnancy, spontaneously subsiding.

Mrs. Hall, æt. 40, of naturally healthy constitution, and fresh-coloured countenance, had a child in the year 1810, ten months after marriage, and in the twentieth year of her age. Her husband died, and she again married in 1814, and eighteen months afterwards had a second child.

About eight years ago she had uterine disturbance to such a degree as induced her medical attendant to tell her she would bear no more children. What this affection was I cannot satisfactorily learn, the practitioner to whom she applied being dead. She says that a purulent discharge continually issued from the neighbourhood of the uterus, and that a large bougie was occasionally introduced up the vagina. From this and the attendant constitutional symptoms she recovered in about four years.

Menstruating regularly, she again conceived about Midsummer, 1830, sixteen years from the birth of her last child, attended, during the early months, with an aggravation of the usual symptoms of pregnancy. These subsided, but recurred towards its close, accompanied with pain in the loins, a tenderness and tumefaction in the right iliac region, pains in the hips, numbness of the right thigh, a disagreeable taste in the mouth, and slight fever.

March 10th. — The predominant symptoms are the shooting pains in the loins, the numbness of the thigh, and the nauseous taste in the mouth, compared by the patient to rotten eggs. There is an enlargement, about the size of a child's head, with rather indistinct fluctuation to the right of the spinous processes of the lumbar vertebræ.

23d. — The pain in the back has been so severe for the last week that the patient has been confined to her bed. There is evidently a deep-seated fluctuation. A puncture discharged about a quart of good pus, with great ease to the patient, but had no apparent influence upon the ovarian (?) swelling. The wound was closed with sticking plaster, and a flannel roller bound round the loins. In the course of the evening, and after some hours severe pain, the dressings gave way, letting out a quantity of matter, nearly equal to that withdrawn in the morning, and with as great relief.

24th. — There has been severe pain in the back, shooting from thence along the course of the psoas muscle, with much bulging in the former part. For the first time, too, an oblong swelling, about the size of a large hen's egg, is observed midway between the crista of the ilium and the os pubis, above Poupert's ligament, and apparently in the direction of the inguinal canal. The ovarian (?) tumor remains pretty nearly in the same state. The contents of the abscess in the back were again discharged, by which the inguinal swelling was lessened.

In the night labour came on, but so reduced was the patient, from want of rest, suffering, and great secretion, that she became alarmingly exhausted after a few hours continuance of labour. The mouth of the womb being fully dilated, and the head of the child at the brim of the pelvis, (too high to admit of the application of the forceps with effect) I judged it more advisable to deliver by turning, than subject my worn-out patient to a repetition of inefficient pains, gradually becoming weaker. I effected this with very little difficulty, and no violence, the uterus scarcely recognizing the presence of my hand. The placenta and membranes were expelled in about a quarter of an hour by the natural contraction of the womb, the latter organ being distinctly felt as a round hard ball in the hypogastric region. Yet the abdomen did not appear lessened, and it was thought by the attendants that there was still a child *in utero*. It was evident, however, that the enlargement occupied principally the right side. After remaining quiet a full hour, I had her very quietly put to bed, and administered thirty drops of laudanum in a little warm wine and water.

25th. — The swelling in the iliac region continues, as do the pains in the hips, the numbness of the thigh, and the disagreeable taste in the mouth. There is about the usual quantity of lochial discharge.

In the evening of the 26th I was sent for in great haste in consequence of a great and very sudden discharge of watery fluid from the vagina, estimated by the attendants at two or three gallons, but admitting of no accurate measurement, as it escaped among the bed-linen. The ovarian (?) swelling disappeared; the pain in the hips, and the

numbness of the thigh, subsided; and, for the first time for a month, the patient had a comfortable night's sleep. From this time she became convalescent; the discharge from the back continued unabated for about a fortnight, and then very slowly, but gradually decreased; a small quantity, however, still remains, with but little pain, and scarcely any inconvenience. The ovarian (?) disease, with its attendant symptoms, vanished; the pulse, which during the whole progress of the case had been accelerated, became more quiet; and the tongue, which had been coated with a white fur, became clean; whilst by nourishment and fresh air she acquired sufficient strength to suckle her child. Both are now, (October) and have been for some months, stout and healthy, the mother having long resumed her ordinary domestic avocations.

In relating this case, it is obviously not with an intention of describing the treatment adopted: that was necessarily very simple, and such only as tended to relieve general and urgent symptoms. This, therefore, I have not deemed it necessary to introduce.

The great peculiarity consists in the spontaneous discharge of a thin and limpid fluid from the vagina, attended with the immediate subsidence of an intumescence in the right iliac region, together with its attendant consequences, pain in the hips, numbness in the thigh, and disorder of the stomach. These symptoms are readily accounted for; the former from the pressure of the swelling upon the anterior branches of the lumbar and sacral nerves, the latter from the universal sympathy which exists between the generative organs and the stomach.

Now it would seem that the right ovary was predisposed to disease in consequence of the disturbance that existed in the uterus years back, when, possibly, adhesive inflammation had agglutinated the fimbriated extremity of the fallopian tube to the ovary, and that the process of utero-gestation had proved the exciting cause to the dropsical effusion, (in which, perhaps, the fallopian tube was implicated) which, by the bursting of the sac which contained it, had been transmitted through the tube to the uterus, and thus effected its escape.

It could not have been dropsical effusion of the uterus, for that would have

required a closure of the cervix during its formation, which would have been incompatible with a constant and free discharge of the lochia. The same may be said of that irritable state of the vessels secreting the liquor amnii to excess, as mentioned by Dr. Mason Good. It could not have been an hydatid, for it must have had an envelope; its expulsion, too, would have required much uterine pain; in addition to which, the uterus was distinctly recognized as a firm and hard tumor in the hypogastric region, totally distinct from that I conceived to be the ovarian enlargement.

It is universally admitted that a vesicle in the ovary bursts from the stimulus of the seminal fluid, and that the ovum is conveyed from thence through the fallopian tube to the uterus; and why, by a sudden movement of the body, or other agent, may not the sac of an ovarian dropsy be lacerated and its contents escape into the uterus?

If, then, this view be correct, it must be considered a very fortunate and rare termination of a disease very little under the control of medicine. Such an event must not frequently be expected.

I have purposely avoided much notice of the abscess, evidently a psoas. It was unusually rapid in its formation and reproduction, and unattended with disease in the vertebræ. It had been punctured in the back before it pointed in the groin. A depending opening would certainly have expedited the healing, but one was already made, and I hesitated making another through the aponeurosis of the abdominal muscles, thereby rendering weaker a part already too susceptible of important diseases.

AMPUTATION OF HIP-JOINT.

To the Editor of the London Medical Gazette.

Glasgow, Nov. 12, 1831.

SIR,

MAY I request the favour of your publishing, in the next number of the *Gazette*, the following case of successful amputation at the hip-joint, which was under my care in the infirmary here during last summer.

I am, sir,

Yours, &c. &c.

JOHN MACFARLANE, M.D.

Senior Surgeon to the Glasgow Royal Infirmary, &c. &c.

Elizabeth Kerr, two years of age, was admitted about 11 o'clock of the forenoon of 6th July last, on account of a compound fracture of the left femur, in its upper third, with extensive laceration of the muscles and integuments. This severe injury was produced, an hour and a quarter before, by the wheel of a loaded waggon passing obliquely across the upper part of thigh. The bone was fractured transversely, a little below the trochanter, and completely denuded of integuments and muscles anteriorly, to within an inch of its condyles. Posteriorly the soft parts were also dreadfully lacerated and contused, especially at the upper boundary of the popliteal space, where the limb was only retained by a narrow flap of integument and muscle. The femoral artery and vein were torn across, opposite the fracture, but the bleeding was trifling, and consisted only of a slight oozing from the latter vessel and from the lacerated surface. There was also a compound comminuted fracture of all the phalanges of the left little finger.

The child was carried to the hospital from a distance of two miles, the injured limb being extended on a pillow. The countenance was pale and anxious, the pulse rapid and feeble, and the body cold. The usual expedients for exciting re-action were promptly adopted; heat was applied to different parts of the body, and warm wine negus administered. A consultation was immediately called, and I saw her for the first time at a quarter to 12. She still lay in a state of collapse, but was quite sensible, and cried bitterly when the limb was examined.

From the nature and extent of the injury, it was sufficiently evident that the child's life could only be preserved by amputation at the hip-joint. This operation I was anxious at once to perform, but from the absence of my colleagues it had to be delayed, and a second consultation summoned at 1 o'clock. At this hour I was favoured with the presence and assistance of my friend, Dr. Perry, with whose concurrence I immediately proceeded to the operation.

An outer and an inner flap were formed by transfixing the limb with Lisfranc's knife, which was passed so closely around the head of the femur as completely to divide all its muscular coverings; the capsular ligament was opened with a scalpel, the bone disar-

ticated, and the limb removed; the femoral artery was effectually compressed by an assistant, and not more than six drachms of blood were lost; five vessels were secured by ligature, after which the flaps were brought together, and retained in apposition by adhesive plaster, compress, and bandage.

During the operation the child was exceedingly weak, and before the wound could be dressed it was in a state of syncope, and appeared to be dying; the pulse at the wrist was imperceptible, and it was even with difficulty the pulsations of the femoral artery in the wound could be discovered; the face was deadly pale, and covered by clammy perspiration; the body cold; the eyes fixed in their sockets; the pupils dilated; and the breathing hurried, interrupted, and laborious. Stimulants were freely administered, and the child was removed to bed, having been about twenty minutes on the table. She lay in a state of collapse and insensibility till 7 p.m. when, after vomiting once or twice, reaction was gradually established. At 8 the stimulants were discontinued; the pulse was 130; skin hot and dry; the fractured finger was now removed, and a poultice applied.

Ol. Ricini, 3ij. et post hor. duas enema domestic. Mistur. Diaphor. c. Vin. Antimon. 3tia q. q. hor.

7th.—The child is not weaned, and has been sucking freely; was much annoyed with startings during the night; pulse 140; skin hot and dry; respiration hurried; no oozing from wound.

Submur. Hydr. gr. ij. et rept. post hor. quatuor. Contin. Mistur.

Half-past 7, p.m.—Has been in a drowsy state since two o'clock, from which she can with difficulty be roused; eyes clear and sensible to light; pupils contracted; increased heat of skin, and flushing of face; troublesome startings; pulse 160, feeble; no stool.

Enema domestic. Abrad. Capill Bladder with iced water to head. Contin. alia.

8th.—Is more alert, and answers questions readily; respiration still hurried, and there is mucous râle in trachea; pulse 160; bowels free.

9th.—Had rather a quiet night, with less starting; tongue cleaner. On undressing wound, flaps were found ad-

hering throughout, except a small portion at upper angle, which is sloughy.

Omit. Medic. Four ounces beef-tea.

11th.—Pulse still very rapid, but febrile excitement diminishing. Edges of wound clean, cut granulations pale.

Vin. Rubri, $\mathfrak{z}\text{ij}$. in dies.

13th.—Was more restless last night, and is troubled with cough, dyspnoea, and occasional vomiting. Mucous r  le is heard over the whole thoracic parietes. Countenance rather sunk; frequently refuses the breast; pulse very rapid and weak.

Mistur. Mucilag. c. Tr   Opii. Calomel, gr. ij. 4ta q. q. hor. Contin. Vin.

Without continuing the diurnal reports, I may shortly state, that the symptoms of bronchitis continued rather urgent till the 19th, when they began gradually to diminish. From the 22d till the 6th of August, although the wound continued steadily to heal, there existed a good deal of irritability of the bowels, accompanied by diarrh  a, and an aphthous state of the mouth. During this period, three molar teeth cut the gum, and ultimately gave relief to the symptoms. The wound gradually healed; the child improved daily in strength and spirits, and was dismissed cured on the 13th of August.

There were several points in the history and progress of this case which rendered the prospect of its ultimate success extremely problematical. The extensive nature of the injury, and the alarming collapse which it produced, might have reasonably deterred almost any surgeon from undertaking, in circumstances so apparently hopeless, the performance of so severe and formidable an operation as that of amputation at the hip-joint. On first examining the injured limb, I was induced to view the case as almost, if not altogether, hopeless. It was only, however, by amputation that the child's life could be preserved; and although I was aware that this operation might, in a subject so young, and already so much sunk by the shock of the injury, be productive of immediately fatal consequences, I considered that I should have failed in my duty had I not recommended and adopted it. I regretted at the time the delay that took place in obtaining a consultation. The child was in a more favourable state for amputation at eleven than at one;

and had it been performed two hours sooner, I am convinced that the shock to the nervous system would have been lessened by its nearer approximation to, and by its becoming in some measure blended with, the shock of the injury. It was evident that the collapse which existed before, and for about five hours and a half after amputation, was not occasioned by loss of blood, but depended on the depressed condition of the nervous system, produced by the injury and aggravated by the operation. With the view of lessening as much as possible the injurious effects of the operation upon the nervous system, I was anxious to perform it rapidly, and with little loss of blood. Both these objects were in part attained. The formation of the flaps, disarticulation of the femur, and removal of the limb, did not occupy a minute and a half, and not more than six ounces of blood were lost. I am no advocate for the hurried performance of operations: nevertheless, it must be admitted, that when the pain and irritation of a tedious and protracted operation come to tell, as they must do, injuriously on a constitution which has already sustained a violent shock, the most serious consequences may be anticipated; and we are certainly warranted, in such circumstances, in expediting the operation as much as is consistent with its safe and efficient performance.

The youth of the child was also inimical to the success of the operation. The physical irritability which exists during the two or three first years of childhood is so great as to render the performance of any capital operation extremely dangerous. I am not aware that there is any case on record in which amputation of the femur at the cotyloid cavity has been performed on so young a subject; and I have been chiefly induced to communicate this case to the profession, in order to shew, that in serious injuries inflicted on young children we ought not altogether to despair of success, even in the most desperate circumstances, but to proceed with those operative measures which the peculiarities of the injury may demand. I must state, however, that I have witnessed amputation of the hand twice on children under three years of age, and in both cases convulsions supervened, and proved fatal in less than twenty-four hours. We would not will-

ingly select such cases for operation, neither should we decline to use the knife when it is absolutely called for.

We had not only the immediate dangers of the operation to deal with in the case of Kerr, but we had also to contend with a series of untoward occurrences during the progress of the cure. 1st. The collapse was unusually severe and protracted; and, as generally happens, was productive of excessive excitement. 2d. The continuance of this febrile excitement, for eighteen hours, produced an affection of the brain, accompanied by partial coma. 3d. The occurrence of bronchitis, which was rather protracted and severe, was another source of danger; and, 4th, the existence of troublesome diarrhoea, with dentition. The child not having been weaned was, I think, also detrimental to its recovery. The continued anxiety of the mother; her absence from her family, and her close confinement in the hospital, occasioned a continued diminution, and, occasionally, an almost complete suspension of the secretion of milk; and as the child refused spoon-meat of all kinds, it must be obvious that she was often but imperfectly nourished.

Since she was dismissed from the Infirmary, she has completely regained her health and strength, and she is now able to move about the house with the aid of crutches.

MEDICAL GAZETTE.

Saturday, November 19, 1831.

"*Lacet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"—CICERO.

MODE IN WHICH CHOLERA IS PROPAGATED.

WE last week laid before our readers a *resumé* of those considerations which had induced us, after mature investigation, to conclude, that the cholera was a contagious disease—by which term we understand, a complaint capable of being transmitted, mediately or immediately, from the sick to the healthy. To our minds the narrative, when examined as one continuous chain of events, is convincing; but to produce its impression, the question must be considered in this manner,—if

we content ourselves with a few links only, or view with microscopic eye certain detached facts—we naturally magnify them into unreal dimensions, and lose sight of the general bearings of the whole. Now this is precisely what the non-contagionists appear to us invariably to do: they bring forward certain cases, in which individuals exposed to cholera have escaped, and draw from them the illogical inference, that those who have been similarly exposed, and taken the disease, have done so from some other cause than the exposure. Let us consider this matter a little farther. One of the persons cut off at Sunderland the week before last, was taken to the hospital; of the nurses employed about the patient, one took the disease, and the others escaped. The only rational deduction from these premises is, that so far as one example goes, they shew cholera to be contagious, but not necessarily to affect all who may be exposed to it. But the anti-contagionists are not content with this: they say, no; the escape of the nurses, who did not become affected, neutralizes the evidence. Now let us apply the same mode of reasoning to the agency of any other influence external to the individuals—let us, for the sake of argument, suppose cholera to arise from one of the many hypothetical explanations which have been offered; *e. g.* subterraneous changes. The nurses inhabiting the same dwelling, must all have been exposed to this same subterraneous incomprehensibility; but as some did not take it, therefore she who did, must have taken it from some other cause than that which left the others uninjured. It is thus quite evident, that no argument can be drawn from the exemption of those who escape, which does not apply to all other supposed sources of the malady quite as forcibly as it does to contagion. Again, it is said that the nurse who died was very much afraid of taking the disease

—a most unfortunate argument for the side it is intended to uphold, because fear is universally admitted to render individuals more susceptible of diseases which are communicable, and serves to explain the circumstance which made her system yield to an impression which others resisted. Nor is there any way of getting over this inference otherwise than by holding, that the nurse died of fright, and not of cholera; but few, we suppose, will be disposed to go as far as this.

We have adduced the preceding illustration, because it has actually been brought forward since our former article was written, as an argument against the accuracy of the views which we adopt; whereas, it proves only—what every one knew before—that all who are exposed to the contagious influence of cholera do not take the disease, any more than all fall sick of small-pox, measles, or scarlatina, who are exposed to their several contaminations. This, however, leads us to make some observations on the nature of the communicating principle, for which neither time nor space served us last week. It appears to us, that the proportion of mankind, who are susceptible of cholera, is smaller than holds good with regard to the other transmissible diseases; but that they who are susceptible, have the susceptibility in a more exquisite degree, so that a much more considerable dilution of the poison becomes necessary before it is rendered innocuous. This dilution generally took place to a much greater extent in India than in Russia, and hence the propagation of the disease by transmission from man to man was much less conspicuous in the former country than in the latter. In India, the spare garments of the inhabitants, their copious ablutions, and the universal admission of air into every portion of every dwelling, tended so much to counteract the influence of the poison, that many were constantly

exposed to it with impunity, and hence the true mode of its propagation long escaped detection; but in Russia, the sheep-skin clothing of the lower orders, which is but rarely changed, the stove system, and the close apartments of all ranks, from which indeed every breath of air is carefully excluded, contributed to present the deleterious impregnation in a more concentrated form, and hence the fact of the disease passing from man to man there, became much more apparent. The result, in both cases, was such as might have been expected. Dr. Russell came from India impressed with the opinion, that the disease was not communicated from man to man; he comes from Russia convinced that it is. Dr. Lawrie, an intelligent surgeon from India, observes, “I feel myself called on to say, that, while in India, and even after I had commenced writing the present remarks, I was convinced that cholera was not contagious. I must candidly confess, however, that a closer investigation of the history of the Indian disease, added to a due consideration of the progress which cholera is still making on the continent, has shaken my previously established opinion*.” Another Indian practitioner presents himself in Mr. Kennedy, who has gone so far as to assume the principle of transmission in the name he has bestowed upon the disease,—that of the “contagious cholera.” And Mr. Orton, known as the author of a most valuable work on Cholera, after enumerating the facts in favour of non-contagion, adds, “These facts appear so clear and strong that if we looked no farther, they would seem to put the matter at rest; but with regard to the general question of the contagious, or (if another term must be used) infectious nature of the disease, *they appear to me no more than dust in the balance against those which may be opposed to them.*”

No country could be more calculated

* Glasgow Medical Journal, November.

than India to prevent the communicable nature of the disease from being forced upon the attention, because the universality of thorough ventilation constantly enabled many to be exposed to the sick without harm, and these daily instances of immunity diverted men's minds from the truth. On the other hand, probably no quarter of the civilized globe could be better adapted than Russia to bring into obvious and unequivocal display the full development of that principle, from the pernicious influence of which the greatest peril is in concentration, and the only safety in dilution. This doctrine cannot be impressed too strongly on the public mind with a view to the common safety. All can understand, that if a dose of arsenic be put into a glass of water, it cannot be taken without almost certain death; that if it be put into a cistern, there would still be danger, though not to the same degree; but that if it were cast into the Thames, the whole town might drink of it with impunity.

That so many escape who are in close attendance on the sick, proves how few comparatively are susceptible of the disease; that so many become affected without obvious exposure, proves how great the dilution is which is requisite to rob the poison of its power over those whose systems render them open to its attacks. It seems clearly established, that approximation to the sick is by no means necessary to the production of the disease, and consequently the links which form the chain of communication are constantly subject to interruption. Thus we are informed by Drs. Russell and Barry, "that neither the near approach nor the immediate contact of an infected individual were indispensable to the infection of a healthy individual." From this it would appear that the influence producing cholera is of a more diffusible, though not less energetic, character than that which emanates from small-pox, or any of the other avowedly infectious maladies.

Now there are two modes in which a poison of this description may be supposed to be conveyed to the previously healthy, without their approaching the sick: first, we may suppose it to impregnate the atmosphere, and be wafted by currents to a distance more or less considerable; and, secondly, that it may be carried by the persons or garments of individuals who themselves resist its impression, or by goods of various kinds. Of both these, numerous illustrations might be adduced, but a few must suffice. Of the former, a striking instance, which we subjoin, is given in the Madras Reports.

"Of two vessels, arriving and remaining at anchor in Madras Roads, one was attacked with the epidemic ten days after arrival there, and the other remained free from it for a fortnight longer; but on the first, in which it was still prevailing, changing her birth, and taking up a situation a quarter of a mile to the windward of the healthy vessel, it was immediately attacked; and those who slept on the side next the infected ship suffered particularly*."

And again: when the disease was raging at a town in Persia, a body of troops passing in that direction "were prevented, by guards situated at the gates, from entering it; but several of them passed the day under the walls. During the following day the disease manifested itself among them, and they suffered from it very severely†."

The above, though strong, are by no means solitary examples of this law; so far otherwise, that it is in accordance with general observation, that places to the leeward of an infected locality were, *ceteris paribus*, decidedly more apt to suffer than others.

The power possessed by those who have been exposed to and imbibed, but without being themselves brought under, the influence of the poison, is a circum-

* Madras Reports, p. 25.

† Med. Chir. Transactions, vol. xii. p. 359.

stance of still greater importance, because more generally doubted, and more calculated to lead to the unsuspected and unintended propagation of the disease. The opinions to this effect, however, and the examples adduced in attestation of its accuracy, are too numerous and too well authenticated to be got rid of by any summary expression of incredulity. Hear the account given by the Captain of the *Bellona*, a Russian man of war:—

“ ‘The *Bellona* frigate, 44 guns, 320 men, had 16 sick of cholera; first case on 30th June, (O.S.):—This man had not been on shore. *The first communication which the ship had with the shore was on the morning of that day, when the captain, some of the officers, and a boat's crew, went to Cronstadt.* In the evening the first man was seized, and in quick succession fifteen others, not one of whom had been on shore. No officer was attacked.’ ”

Again, we are informed by Captain Baron Loeventhall, that

“ ‘The *Phoenix* brig had been stationed for two months midway between Cronstadt and Peterhoff, about six versts, or four miles, from either, to the S.E. of the former, for the purpose of telegraphic communication with his Majesty. She continued in this situation to the 15th of July, in perfect health, though she sent her boat twice a week to the fortress for provisions. On the 15th she took up her station one verst to the S.W. of the town, and had two men attacked with cholera on the 17th. Neither of these men had been on shore. The surgeon only had gone to Dr. Lange's hospital on the 16th, for the purpose of observing the cholera, which he had not seen before. The doctor said to him, ‘*You had better not remain here long, else you may carry the disease to your ship, and I shall be responsible*’.”

Another circumstance, which tends strongly to establish the same position, is, that cholera first broke out among the Poles after an engagement with the Russians; and a second time, in a different quarter, the Polish army, which

had been separated from its own sick, was again affected with the disease, immediately after an engagement. Now, from the acute and violent nature of the malady, it cannot be imagined that those actually labouring under it could go to battle; the legitimate inference, therefore, is, that they carried with them the contamination, whatever it may be, and communicated it to the opposing army with which they came into contact, not merely at the moment of contest, but many of them subsequently as prisoners. “It seems tolerably well ascertained,” says Dr. Russell*, “that the cholera has not broken out spontaneously in any place without communication by persons or effects coming from infected places; but it is somewhat singular and unaccountable that the disease has appeared in situations where the persons arriving did not themselves labour under the disease at the time of their arrival.” Certain it is, that persons not obviously labouring under the disease appears frequently to have been the medium of its communication; and this is a very important fact, both as serving to account for the difficulty which frequently exists in tracing out every link in the chain by which it is transmitted from man to man, and also as affording a necessary caution with regard to the degree of intercourse to be held between the healthy and the attendants of the sick. Generally speaking, the period intervening between the effectual exposure and the attack is very short, not exceeding a few days, but in other instances an individual may be exposed to the virus, without its influence being developed for a considerable interval, and he may thus transport it to a greater distance. We are informed that “a convict was sent from a village where cholera prevailed, to Chanda, eighty miles off. Two hours after his arrival he was attacked, and speedily

* Official Papers, p. 54.

* Private letter.

died. Three of the four persons who carried him to the grave, and another who attended them there, were the next sufferers; and shortly the disease became general*."

The inference from all this is, that an individual may commence a journey apparently well, and travel on transmitting the disease to others as he passes; or, on the other hand, if on board ship, he may have already escaped the first stage of cholera, and be on the sick list merely as labouring under fever. "Nothing (say Drs. Russell and Barry) is more certain than that persons may come to the coast of England, apparently labouring under common feverish indisposition, who really and truly are cases of cholera in the second stage†." These observations, we trust, will receive the attention they deserve from all concerned in the planning or execution of measures connected with the public health: even those who think differently from us on the subject of transmission, will still probably admit, that while any uncertainty is attached to the question, the public are entitled to the benefit of the doubt.

CHOLERA AT SUNDERLAND.

THE disease at Sunderland seemed for a few days to have been checked, and the fears which its announcement excited were quickly subsiding—indeed many expressed their conviction that *the* cholera had not been there at all. When, however, we call to mind the capricious and insidious manner in which the pestilence has repeatedly behaved abroad, we fear that the confidence with which its immediate disappearance is inferred, is at least premature. In a place so dependent upon its trade, and with so many interested in concealment, from the Noble correspondent of the *Standard* downwards‡, the difficulty

of getting at the truth becomes prodigious. Indeed the most contradictory statements have been put forth, on the authority of the medical men at Sunderland, with regard to the disease and its origin. They are very anxious to prove that it was not imported, and that it is not of a contagious nature. They add further, that the town is more healthy than it usually has been at this season of the year. However, it remains undisputed (only because it is indisputable) that suspected vessels were suffered to come up the river, through the shipping to the Wear, to perform quarantine; and that at least one such vessel had left Hamburgh after the disease was acknowledged to be there. It farther appears, that in Sunderland the disease first broke out among persons connected with the shipping, and spread to several members of the same family; while a nurse, who assisted to remove the body of the first patient who died in the hospital, became affected with the malady in a few hours after. Now, without going farther, we crave leave to ask, how the sudden appearance of a disease, which carries off, within a few hours, more than one-half of those attacked with it, is in their opinion to be accounted for, in a town *unusually healthy*? and by what train of reasoning they have been able to come to the positive conclusion that the vessels from the infected place did not bring it? One question more, and we have done. What kind of *diarrhœa* may that be to which several sudden deaths are set down, at a time when the town is "*unusually healthy*?" Dr. Daun complained, in his reports, of want of co-operation, and it is quite evident that concealment to a considerable extent was, and probably still is, adopted. Meantime he has positively declared the disease to be *the* cholera, whatever its origin may have been, and whatever its future course; an opinion in which the Central Board in London fully

* Mr. Montgomery. Medical Repository, May 1826.

‡ See the Marquess of Londonderry's letter in the newspapers.

concur. Although held at Sunderland, as at almost every other place when actually present, not to be communicable from man to man, the utmost precautions are taken to prevent the operation of the contagious principle. This is all we want: be practically contagionists, and we care not a rush for theoretical differences of opinion.

THE COURIER v. THE MEDICAL GAZETTE.

THE Courier has replied to our exposure of their inconsistency last week, but in a subdued tone, and without being able to show that we were wrong on a single point; in fact, the case did not admit of it. They say it is "impertinent" to call Dr. Johnson's series of letters, in their paper, "protocols:" we know, however, that, in expressing our disapprobation of medical men embracing the opportunity afforded by public excitement, to bring themselves forward through the medium of the daily papers, we do but echo the sentiments of the profession at large. It is a system of advertising, let gentlemen disguise it as they will, and one against which we always have and always shall set our faces, come from what quarter it may. Dr. Johnson, we observe, is now a "contingent contagionist," and he talks

of cholera being not "*very infectious*," *à la bonne heure*: if infectious at all, those on whom the attempt to exclude it devolves, ought not to be told, that they would be held blameless, though the disease should pass their boundaries. As to the rest, no man regards the disease as necessarily communicated to those exposed to its influence, except other "contingencies," such as predisposition, conspire to give it effect*.

BOARDS OF HEALTH.

THE new arrangements connected with the public health, which we announced last week, have been carried into effect. We understand that the members of the original Board are to constitute a Committee of reference, for the guidance of the Privy Council, with regard to medical questions, on such occasions as their advice may be deemed requisite; while the new, or "Central Board," will devote their whole time to the details, and take upon themselves the entire executive department.

LOUIS-LE-GRAND'S PRESENT TO HIS APOTHECARY.

THERE is at Mr. Garden's, the chemist, in Oxford Street, a superb vase of rich-toned bell-metal—a specimen of the age and munificence of Lewis the 14th. It is a noble mortar, measuring nearly two feet in diameter at the mouth, and weighing upwards of two hundred and eighty pounds—presented, with characteristic propriety, by the *Grand Monarque* to his beloved state apothecary. In the founding, the following inscription was cast upon it in relief:—"Charles Angibaud, M^e. App^e. et Ordinaire du Roi. A Paris, 1678:" this goes round it beneath the upper margin. On the body is a shield of emblematical heraldry, having reference to the tree of life, and supported on either side by the arms of France. Two rams' heads project from the body by way of

* Besides one death of common cholera.

† Besides one death of diarrhœa.

* In our last number, article headed "Courier v. Medical Gazette, p. 214, for 'the Editorial writers,' read 'Editorial authorities;'" and in the quotation from the Times, at the conclusion, for "(provided there be time)," read "(provided they be timely)."

handles, though, if M. Angibaud could lift it by them, he must have been able to effect more than any two of his descendants, "in these degenerate days." The whole is in the most beautiful state of preservation, though it bears marks of having seen some service too, as no doubt it should, like other *mortars* of the days of Lewis the Great.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Nov. 12.

DR. STEWART IN THE CHAIR.

Cholera.

DR. JAMES JOHNSON announced that he had in his possession a letter of Dr. McWhirter's, of Newcastle, which he would beg of the Chairman to read.

The Chairman then read the letter, the substance of which was, that the writer and some other physicians at Sunderland, had had a special interview with Dr. Daun, and *extracted* from that gentleman the opinion, that there was *no proof* of the cholera having been imported into the town by infringement of the quarantine precautions. Dr. McWhirter also mentioned, that there were *two* nurses employed about the corpse of the patient who had died of cholera at the infirmary; that the one who sunk under the supposed infection had been greatly alarmed; the other one was not frightened, and escaped.

DR. J. JOHNSON resumed, by observing that these were important facts; and that, coupling them with the bulletin of the night, that but one more case had occurred since the last announcement, he could not help thinking that a *little* too much alarm had been excited. There were circumstances under which cholera might be considered as occasionally contagious; but if ever those circumstances did exist anywhere, it was at Sunderland, where the lower orders were continually drinking spirits, and the quarters where they resided were the filthiest that could be conceived. Saffron-hill and St. Giles's were palaces to them.

DR. SIGMOND was glad to find Dr. Johnson beginning to entertain right notions on the subject of contagion.

DR. J. JOHNSON.—"I was always an advocate for *contingent* contagion."

DR. SIGMOND could not desire a more

satisfactory avowal. The most decided contagionists held no more. The *contingency* existed in the predisposition, and some few other circumstances which were generally admitted.

MR. KING rose to announce himself a contagionist; but he considered *all* diseases to be contagious as well as the cholera morbus. The honourable member then entered into a profound argument to prove that morbid matter existed in the body of every person who was sick, and therefore might be communicated to somebody else. Certain other remarks which fell from the honourable member induced

MR. HUNT and MR. DOUCHEZ to give their opinions on the communicability of typhus fever, and specific diseases, by contagion.

MR. SEARLE being generally called for, rose, and expressed his willingness to communicate whatever he knew on the subject of cholera. He denied that any of the medical attendants on the sick, so far as he could know, and he had ample means of knowing (placed as he was at the head of one of the chief hospitals in Warsaw), ever suffered from the complaint. There was one apothecary's boy, indeed—a drunken, idle rascal—who fell a victim to it; but none of the physicians were attacked, and they were very numerous from all parts of Europe. It was not true that the members of the French medical commission were boys, as asserted in a certain periodical; they were mostly professors—and such indefatigable men he (Mr. S.) never saw. They performed a thousand experiments upon themselves; they inoculated their persons, tasted the excretions, &c.; they fed pigeons, dogs, and cats, upon the offal of the sick, inoculated them, &c., yet none of the consequences ever tended to prove that the disease was propagated by contact or infection. He dwelt considerably upon the fact of his own immunity, notwithstanding his perpetual and laborious attendance upon cholera patients, in all stages of the complaint; he had frequently been obliged to lie down on the hospital beds, debilitated with his labours—attending from an early hour in the morning until ten o'clock at night; nor could he always procure perfect ventilation and cleanliness: coming to the hospital sometimes unexpectedly, he found the windows close shut, and various things in the filthiest state. He spoke altogether from facts which

had fallen under his own personal cognizance; yet he would decline to announce himself either a contagionist or non-contagionist—though the evidence, in his mind, certainly weighed in favour of the latter side of the question.

DR. GRANVILLE, after expressing his satisfaction at Mr. Searle's communication, requested that gentleman to inform the Society further, what he knew relative to the battle which was said to have infected the Poles.

MR. SEARLE explained, that the Polish troops had previously made a forced march of twelve German leagues, or about fifty English miles; they captured a large body of Russians, certainly—but they encamped in a marsh, and the mortality, even on the first night, was above fifty. He thought that too much stress was laid upon the circumstance of the hardships of the Poles. Why, he would be glad to know, was it always stated that the Poles were infected by the Russians on these occasions, and not the Russians by the Poles? He had heard it jocularly observed by a distinguished person in Poland, that this complaint of the cholera was one of the best things that had ever happened his countrymen.

PROFESSOR BURNETT, though in common with the other members of the Society, he was much obliged to Mr. Searle for his kind communication, yet could not but confess himself unconvinced by that gentleman's remarks. He had been much more impressed, on the last night of meeting, by the able arguments of Dr. Macleod; who had shewn that, though many (perhaps the majority) of the individuals who had seen the disease in India, had in their reports subscribed themselves non-contagionists, yet the three great Boards had come to the opposite conclusion. Nor was the Bengal Board an exception; for though Mr. Jameson, the individual who drew up the report for that Board, professed himself a non-contagionist, yet, in the body of the report, he stated his opinion that, though the disease was not communicable from man to man, it was so from one body of men to another body of men! Then there was the disease travelling simultaneously northward by the Volga, and southward by the Don, and in the teeth of the winds; there was also the disease distinctly shut out of Teheran along with the caravan, and forced to go onward to a more distant

locality. The fact, too, of the village which had been one half ravaged by the disease, and the other half preserved by a barricade, was very convincing. The learned Professor then proceeded to expose the quibbling of the non-contagionists, who were now driven to the admission of a modified or *contingent* contagion. He illustrated the nature of predisposition and infection by reference to the growth of seeds; and, in conclusion, dwelt upon the advantages of precaution: *Melius est sapè cavere quam pati semel.*

DR. GRANVILLE rose to reply to some of the arguments of Professor Burnett, and complained of the treatment which his (Dr. G.'s) party received from the contagionists. He particularly alluded to the *tranchante* manner in which the Medical Gazette of that very day disposed of the non-contagionists and their opinions. The learned Doctor now drew from his pocket a newspaper containing the propositions of Drs. Russell and Barry, relative to the contagiousness of cholera, and endeavoured to shew that these gentlemen thought exactly on the question as he did!—(Surprise and laughter).

DR. GREGORY moved an adjournment, in consequence of the lateness of the hour, and wished to know whether it would not be rather better to exchange the question of the communicability of the disease for that of its nature and treatment?

DR. COPLAND was proceeding to make some remarks, when the meeting broke up, as we understood, with the intention of resuming the debate on Saturday next (this night).

The room, during the evening, was thronged with members and visitors: indeed we never recollect an attendance so full.

CLINICAL LECTURES,

Delivered in the Dispensary of the London University,

BY

DR. ANTHONY TODD THOMSON.

LECTURE V.

November 10, 1831.

Epilepsy—Chorea—Lumbago.

GENTLEMEN,—There are two cases of epilepsy at present on the books of this esta-

blishment. The one, that of a girl, about fourteen years of age, of a melancholic temperament, with black, straight hair, and sallow complexion, in whom the disease has existed for several years; and although the frequency of the attacks has been much diminished by the means which have been employed, yet there is little hope of the disease being ultimately cured. Indeed, from the physiognomy of the patient, there is every reason to fear that the result of its continuance will be a state of fatuity. Tracing the history of this case, it appears "that the disease may have originated from a blow upon the occiput, which the girl received six years ago, as the epileptic paroxysm displayed itself soon afterwards, and has continued ever since, with short intermissions. In this case, it is probable that the injury done to the brain may have produced a predisposition to the disease, but as the seat of the mischief is beyond our reach, it is not likely to be removed. The second case is that of Arthur Leny, a green-grocer, who was admitted on the 27th of October: a case to which I have already twice alluded. I have stated that the most singular circumstance in the attack of this case, in which the epileptic paroxysm first displayed itself twenty-three years ago, is the long period which intervened between the first attack and the second, which did not occur till seven years afterwards. Since that time, until within two years ago, the patient suffered generally two or three attacks every year, which, however, were of a slight nature; but two years since they became more frequent, and for a few weeks prior to his application at the Dispensary, he seldom escaped having three or four attacks during the twenty-four hours. The remedies which have been employed, and to which I shall afterwards direct your attention, have been so far successful as to check the frequent recurrence of the fits, none having taken place since the day after he began the use of them.

In all cases of Epilepsy, there appears to be a peculiar predisposition of the person's system—an augmented susceptibility of impression in the brain, which may be denominated the *Epileptic diathesis*. Various circumstances, therefore, which in the ordinary states of the habit, produce little or no effect upon the nervous system, excite it so strongly in those labouring under this diathesis, that convulsions, and spasmodic action of various kinds, may result. In some individuals, particularly in females, hysteria is the consequence; in others, ordinary convulsions may take place; while in others, Epilepsy is produced. The usual causes to which Epilepsy is ascribed are either injuries done to the head, preternatural growths of bone from the skull, or other mechanical causes of irritation in the head. It is not, however, necessary that the irritation be

confined to the brain: cases having occurred in which the disease has been traced to mechanical irritation on nerves out of the cranium. De Haen, for instance, has recorded a case in which it arose from a gangliform concretion adhering to the phrenic nerve. Dr. Short mentions one which was cured by the extraction of the irritant, a tumor, which pressed on the tibial nerve; and the Memoirs of the Medical Society of Geneva describe a fatal case, that evidently arose from an osseous body, about the size of a small nut, with a rough surface, which pressed on a branch of the sciatic nerve. Worms also, or other morbid irritants in the intestinal canal, acting by sympathy upon a highly-susceptible state of the brain, are exciting causes of Epilepsy. Sometimes, however, the exciting causes are of a mental kind, such as sudden grief, violent passions, or terror; or occasionally the attacks can be referred to the retrocession of disease; such, for example, as repelled gout, or cutaneous eruptions; and occasionally to uterine irritation, in which case they may be complicated with hysteria.

The variety of the disease to which I would refer the case under consideration, is that which is termed Cerebral Epilepsy; and I am disposed to regard it as the result, in this instance, of sudden gusts of passion—of a very fretful temper. I am induced to conclude that this is the fact, from strict inquiry into all the circumstances which might have induced this attack, and from having found nothing which would lead me to refer it to any mechanical irritation, or to repelled disease. I can only attribute it to some mental emotion; and the physiognomy of the individual indicates anything but a good-natured and calm disposition. The effect of mental causes in producing Epilepsy was known at a very early period, and obtained for the disease its Latin appellation—*Morbus Comitialis*—from the circumstance of its being by no means an unfrequent result of the high state of excitement produced by the harangues of the Roman orators, in their popular assemblies. By this man's account of himself, also, it appears that he has had much to fret him, and were it possible to trace it, we should probably find that the first paroxysm originated in a gust of boyish passion.

That the disease is Cerebral Epilepsy, is distinctly pointed out by some symptoms which seldom accompany any of the other varieties of Epilepsy: for instance, the constant winking, or nictitation, which still continues, although the fits are suspended; and the giddiness, which also still remains in the absence of the headache. During the fortnight that the paroxysms were of frequent daily occurrence, the patient complained of severe headache; an occasional loss of sight for some time after each paroxysm, and intolerance of the light of a candle or a fire.

These symptoms sufficiently point out the state of the cerebral organ, and with the predisposition which obviously exists, it is not difficult to comprehend that irregular nervous action and resulting convulsions would follow any mental emotion sufficiently violent, either to determine a sudden rush of blood to the head, or to produce sympathetic congestion in the brain.

We know that, in some states of apoplexy, depending on transitory fulness of vessels, epilepsy is not an unfrequent accompaniment; and in the direct ratio of the strength of the epileptic tendency, is much blood-letting unnecessary. Another reason for suspecting mental irritation, rather than permanent fulness of vessels, to have been the exciting cause in this instance, is inferred from the small frequent pulse and singing in the ears, which were present at the time the patient first applied for advice.

In none of the fits does he recollect having experienced any peculiar sensation which might be regarded as its harbinger; neither have the paroxysms kept any stated periods, or made their attack at any particular hour of the day.

In the treatment of the first case which I have mentioned, the only remedies that appeared to be productive of benefit were active purgatives and the introduction of an issue in the neck. The issue is still discharging, and when the bowels are freely open the recurrence of the paroxysms is comparatively distant. I am also inclined to attribute some advantage to the girl being kept in constant occupation, so as to divert, as much as possible, her mind from the contemplation of the disease. Before she applied to the Dispensary, the mother conceiving that her daughter was in a disease which required rest, allowed her to remain in a state of inactivity; but since she was informed that this was improper, and since the girl has been occupied in the ordinary duties of her station, the paroxysms have been less frequent and decidedly less severe. Previous to the introduction of the seton, all the usual means were employed without any obvious advantage. From the state of apathy in which she appeared to be, and from there being a manifest aura epileptica, dry cupping along the spine, stimulant embrocations, and powerful anti-spasmodics, both of a vegetable and mineral kind, were freely tried. It has generally been supposed, that we are to look for some local irritation in the part where the aura epileptica arises; but I have have had sufficient reason to think, that this symptom is as often an accompaniment of the disease, when it depends on general constitutional derangement, as on local irritation. My chief reason, however, for ordering the cupping along the spine, was an idea that there was disease existing there, as the limbs seemed often to give way, prior to the ap-

proach of the fit; and I knew, from the dissections of Mons. Esquirol, that affections of the spine, particularly softening of the cord, has been detected in post-mortem examinations of Epileptic cases. The hip-bath daily, and mercurial alteratives, were also employed for nearly two months, without any benefit; indeed, nothing seemed to check either the severity or frequency of the paroxysms except the purgatives, the seton, and the mental occupation.

In the treatment of the second case, although no permanent plethora manifestly existed, yet I considered it necessary to unload moderately the vessels of the head, by cupping behind the ears. Eight grains of Calomel were directed to be taken immediately afterwards, and to be followed by a brisk cathartic. On the 29th of October, two days after he had used these remedies, he had had no return of the epileptic fit; but from the feelings which he then described—the singing in the ears, the nictitation, and the sensation of wind being in the head—I was induced to continue the purgative system, not so much with a view to carry off any existing acrimony in the bowels themselves, as to set up in them a degree of counter-irritation, which might operate by lessening the irritability of the brain; and so far it appears to have been successful.

I would take this opportunity of remarking to you, gentlemen, that, not unfrequently, a course of cathartics alone has cured epilepsy; and although Dr. Hamilton, who revived the attention of the profession to the influence of Cathartics in Epilepsy, perhaps expected too much from their employment, yet the public owe him a debt of gratitude for expelling the prejudices against the employment of Cathartics, which prevailed for nearly a century before his time. You will find, in his work on purgatives, many cases illustrative of their powerful influence in the treatment both of this and several other nervous affections. The use of purgatives, however, in Epilepsy, is not of modern date; you will find it insisted upon by Celsus, who says—"Necessarium est, ducere alvum, vel nigro veratro purgare, vel utrumque facere, si vires patiuntur." The choice of the Cathartics in Epilepsy, is a matter of some importance: where we suspect the existence of mechanical irritation in the head, those which tend to unload the vessels of the system generally, and thereby to diminish the quantity of circulating fluid sent to the head, are the best adapted to fulfil the indication in view. Where worms are supposed to be present, as we generally find that they are either ascarides or tania, perhaps the rectified oil of Turpentine, in large doses, should be preferred; and when, as in the present instance, our object is not so much to unload the bowels and improve the secretions as to produce a re-vel-

lent effect, or to determine from the head, I prefer very moderate doses of Calomel in combination with Camphor and Henbane, given two or three times a-day, and, in the intervals, small doses of the common Senna mixture, with Wine of Colchicum and Camphor Julep. My object in prescribing the Calomel and Colchicum is to favour the free excretion of bile into the duodenum, so as to afford a general stimulus to the whole intestinal canal; whilst, at the same time, the Camphor and Henbane may moderate the general irritability of the nervous system. The Henbane has one advantage over all other narcotics—it does not confine the bowels; and there is no other which I would prefer, unless where the epilepsy has followed a repelled eruption; in which case, I should be disposed to employ the extract of Belladonna, from its known property of producing a scarlet efflorescence on the skin, owing to its peculiar action on the cutaneous capillaries. It is, however, but candour to say, that as I have never seen Epilepsy proceeding from such a cause, I have had no experience of the effects of Belladonna; and therefore my idea of its proving beneficial must be regarded as conjecture.

As no fits had returned on the 5th of November, and although the headache had completely disappeared, there was still giddiness and constant winking of the eyes, I was induced to order, in addition to his former medicines, moderate doses of the arsenical solution.

In no disease has a greater variety of tonics been tried than in Epilepsy; each has had its day, and the greater number have sunk into merited neglect. I may safely assure you, that you will derive no benefit whatsoever from the use of any of the vegetable tonics. On the contrary, many of them, in particular Bark and the salts of its alkaloïds, appear rather to have done mischief. Indeed, in all cases in which the object of prescribing a tonic has been to allay irritability, and to diminish the spasmodic tendency, vegetable tonics have been found inefficient. Yet they are still used; and it is melancholy to observe that a credulity, worthy of the worst periods of superstition, continues to display itself in modern times, and that medical practitioners can be found weak enough to place confidence in the Mistletoe and similar remedies. Almost all the metallic tonics have proved more or less beneficial; amongst these the preparations of Zinc, Copper, and Silver, have been most generally approved. As far, however, as my own experience authorizes me to judge, I do not place much confidence either in the Oxide or the Sulphate of Zinc, although in the use of both the doses have been carried to their highest extent. I have given six and eight grains of the Oxide, and fifteen of the Sulphate of Zinc, three times in the twenty-four hours,

for many successive days, without any very perceptible advantage. As to the Salts of Copper, I have always regarded them with a suspicious eye, on account of their poisonous qualities, and therefore probably may not be able to give a fair opinion concerning them, as I have never carried either the Sulphate of Copper, or the Ammoniated Copper, beyond a very moderate dose.

Soon after Dr. Power made his experiments with the Nitrate of Silver in St. Bartholomew's Hospital, I was induced by his success to try that salt in two cases of Epilepsy; in one the dose was carried to the extent of six grains three times a day; in the other to eight grains; and to its use the disease yielded. But I confess that I have been prevented from employing it since by the dread of the known effect which it has in colouring permanently the skin; and I am of opinion the more effectual it is in small doses, the more likely is this discolouration to be produced. I can scarcely believe it possible, that any stomach can bear even six grains of the Nitrate of Silver for a dose, unless a considerable quantity of free Muriatic Acid, or of the Murates, be present in it. Now, if this be the case, the greater part, or the whole, of the Nitrate, will necessarily be converted into an inert Muriate; and therefore only that which remains undecomposed can operate as an effective tonic. On the contrary, if a small dose produce a beneficial effect, there is reason for supposing that it has entered into the system; and, under such circumstances, we can have no certainty that it may not be decomposed in the rete mucosum, and permanently retained there as a Chloride, affording, from the action of light, and that of Sulphuretted Hydrogen, not unfrequently exhaled from the skin, the dark colour which it has unfortunately too often produced. I hold an opinion, that such an effect is likely always to take place, when the rete mucosum actually exists in the European; for it is there that colouring matters of an insoluble character, even when introduced mechanically under the skin, remain unabsorbed for life; and as the Chloride of Silver is insoluble in the animal juices, it will necessarily follow the same law when formed in that organ. How far the administration of diluted Nitric Acid, at the same time that the Nitrate of Silver is given, might prevent such an event, experience has not enabled me to determine. These being the reasons which have prevented me from prescribing some of the metallic salts, I prefer the Arsenical solution for two obvious reasons. In the first place, its influence in allaying irregular nervous action has been well established, in the treatment of intermittent fevers; secondly, because it has effected decidedly beneficial results in the Epileptic attacks of the delicate, and in worn out habits; in the drunken Epileptic when ple-

thorax is not present, and in many other spasmodic diseases not attended by plethoræ. It is not so likely to interfere with the purgatives as the Salts of Zinc or of Copper, and it does not accumulate in the habit, nor has it the disadvantage of colouring the skin, which may attend the administration of Nitrate of Silver. I do not wish you, however, to suppose that Arsenic more than any other metallic salt, is applicable to every case of Epilepsy; such an idea would mislead you. Much depends on the circumstances attending the case, and the constitution of the patient. In the present instance the spare habit of this man, and the absence of plethoræ, seem to indicate its use, even although the fits observed no regular periods. Our patient has already benefited by its use, and he will, I have no doubt, obtain a permanent cure.

You may, perhaps, gentlemen, be surprised that I have not noticed any of the direct Antispasmodics in mentioning the general treatment of Epilepsy; but I have never seen the smallest benefit accrue from the administration of any of them, except Musk, which is too expensive a remedy for a Dispensary. In one very severe and unmanageable case, of several years' continuance, which came under my care in private practice, I gave Musk, in gradually increased doses, to the extent of half a drachm, three times a day, with most decided benefit. The fits, which for several years had amounted to two or three daily, became gradually less frequent and less severe, until, the full dose of musk being given, and continued for some time, the fits were suspended for five months, and they might not, probably, have returned again had the patient lived, but he soon afterwards died of typhus fever.

As in the treatment of every other disease, Diet and Regimen require to be attended to in that of Epilepsy; the former should be moderate in quantity, not more than the stomach can fully master, of a nutritious quality, but light: all fermented liquors should be avoided. Exercise ought to be regular, but not carried to fatigue; and the mind and spirits should be maintained as far as possible in a cheerful and elastic state.

Chorea.

Since I last lectured, another case of nervous affection, *Chorea*, has been admitted. The patient, Elizabeth Brady, aged seven years, with light hair, and of a sanguine temperament, tall, and spare in her habit, was in perfect health until about a fortnight ago, when immediately after her return from school, the disease displayed itself. She complained that she could not sit still; there was constant jactitation of the arms and legs, and uninterrupted movement of the fingers, a rolling of the head, and twitchings of the

muscles of the face, which continued even when she was in a recumbent position. She has scarcely slept at nights, not more than half an hour at a stretch; then generally awakes with a start, and the movements of the limbs and head immediately commence. She walks with great difficulty, the limbs twisting in various directions, so that she requires to be held up to prevent her from falling. Her speech is a little impaired, and her eyes have a very peculiar, rolling character. The bowels are open; the urine is high coloured; the pulse small, feeble, and quick; and the tongue slightly furred. The alvine evacuations are of a dirty, unnatural colour; and the perspiration has a peculiar offensive odour.

My first object in this case was to remove all acrimonious matter from the bowels, and to improve the character of the secretions. My second to restore the tone of the habit, and thereby overcome the spasmodic tendency. With these views, the patient was ordered a powder, containing five grains of Calomel, and twelve of Jalap, to be taken immediately, and repeated at the distance of eight hours, for three times successively; after which, she was directed to take ten grains of the Carbonate of Iron, and three of the powder of Conium, every third hour during the day; to observe a light diet; and to have friction applied along the spine and over the abdomen, as she was incapable of taking exercise. As the girl has not made her appearance again, I must reserve my remarks upon the case for our next lecture.

Rheumatism—Lumbago.

The cases of Smith and Sparrow have been discharged cured, and as West has not again paid us a visit, I have every reason to believe that he also is well. One case of severe Lumbago has been admitted since these cases, and the pain still continues with little abatement. The patient is an old man, with a broken-up constitution and of irregular habits; he has been cupped across the loins twice, blistered, and put under a course of purgatives, with Calomel, Colchicum, and Opium, and, latterly, he has taken also a Terebinthinate mixture, with large doses of the Tinctura Conii. The pains, however, continue. Although he has been strictly enjoined to observe regularity in diet, yet, I am apprehensive, that these orders are not obeyed, and to this circumstance, in part, may be ascribed the little benefit which treatment has produced in this case. It is one of many instances in which the influence of medicines, otherwise most effective, is completely counteracted by the abuse of dietetic stimulants. Such is also the case with the woman Eadwell, to whose case I formerly alluded as an illustration of that mixed form of rheumatism and gout, com-

mon'y called rheumatic gout As long as this lady remains sober, she improves; but as habit has confirmed her irregular tendencies, and her hours of sobriety are, "like angel visits, few and far between," I have little hope of being able to effect a cure in her case.

SANITARY HINTS RESPECTING CHOLERA.

Council Office, Whitehall, 14th Nov. 1831.

Sir,
THE Central Board of Health having maturely weighed all the information which has been transmitted to them relative to the progress of the Asiatic Spasmodic Cholera in various parts of Europe, but more particularly guided by the conclusions on this head, to which Drs. Russell and Barry have arrived after a five months' careful and laborious observation of the character of that disease in those parts of Russia which they have visited, beg leave to suggest for your consideration the following sanitary hints:—

I.—As to Precautionary Measures.

In order to ensure the adoption and realize the benefit of any system of sanitary arrangements in a large community, the first essential point is to divide that community into subordinate sections, and to form District Boards of Health, each to consist, if possible, of a resident clergyman and a number of substantial householders, and of one medical man at least.

These Boards should be charged with the following duties in their respective districts, viz.:

1st, To appoint inspectors. Each inspector to visit daily, and to inquire carefully after the health, means of subsistence, cleanliness, and comfort, of the inmates of, say, (100 houses, more or less,) according to local circumstances.

2dly, To receive and examine the reports of these inspectors, which should be made up to a given hour on each day.

3dly, To endeavour to remedy, by every means which individual and public charitable exertion can supply, such deficiency as may be found to exist in their respective districts in the following primary elements of public health, viz. the food of the poor, clothing, bedding, ventilation, space, cleanliness, outlets for domestic filth, habits of temperance, prevention of panic.

4thly, To report to their principal Boards respectively on the above heads, as well as on the actual state of health of their districts.

The subordinate divisions of each district ought to be numbered or lettered, and each

district named, the names of the members of each Board, or of the medical men attached to each, and of the visiting inspectors employed, should be placarded in conspicuous places.

Principal Boards of cities, towns, or parishes, to report directly to the Central Board in London:—

1st, On the actual state of health of their whole population.

2dly, On the precautionary measures already carried into effect.

3dly, On the measures contemplated.

4thly, On suspected sources, if any there be, from whence this particular disease might possibly spring.

With regard to precautions as to intercourse with suspected or really infected persons or places, the Board are confident that good sense and good feeling will not only point out, but morally establish, as far as may be practicable, the necessity of avoiding such communication as may endanger the lives of thousands.

But they strongly deprecate all measures of coercion for this purpose, which, when tried upon the Continent, invariably have been productive of evil. The best inducements to a prompt acknowledgment of the disease having entered a family, as well as to an early and voluntary separation of the sick from the healthy, will always be found in the readiness and efficiency with which public charitable institutions attend to the objects noticed in S. 3.

It is with much satisfaction that the Board feel themselves authorized to declare, and it will no doubt be highly consolatory to the public to learn, that under proper observances of cleanliness and ventilation, this disease seldom spreads in families, and rarely passes to those about the sick, under such favourable circumstances, unless they happen to be particularly predisposed.

It will not therefore be necessary, where there is space, and where due attention is paid to cleanliness and purity of air, to separate members of families actually affected by the disease, nor to insulate individual houses, unless in cases of crowded, filthy, badly-ventilated habitations, and other contingencies, which involve the health and safety of all.

It having been proved, by ample experience, in more than one city in Europe, that the fitting up and furnishing of hospitals for the reception of the poorer classes supposed likely to be attacked by the disease, at a period too long before its actual breaking out, has been productive of great waste of means, by the spoiling of various articles, and the consequent want of wholesome accommodation when most required, the Central Board would recommend that proper and sufficient house room only be secured

and prepared in the first instance, and that the charitable be called upon only to *pledge* themselves to furnish at a given notice such articles of bedding, furniture, &c. or the value of them, as they would have at once contributed.

By this means the deterioration of perishable articles will be avoided, and should the district entirely escape, the contribution will be saved.

The situation which the Board would recommend for temporary Cholera hospitals would be, those most detached, insulated, and thoroughly exposed to free and open air; the description of house, such as would admit of the most perfect ventilation and cleanliness, and the largest space around the sick.

The Board would recommend, when a family is reported to be in an unhealthy state by the sub-inspector, and the disease confirmed to be Cholera by a medical member of the District Board, that the head of such family, if unable to afford proper accommodation at home, be advised to send the sick person forthwith to the temporary hospital, and that the other members of the family be supplied with such additional means and comforts as their state may require to enable them to resist the influence of the infected atmosphere in which they live.

II.—Medical and Dietetic Precautions.

These will be found of considerable importance, from their contributing to prevent or diminish the susceptibility to infection which individuals may possess at the moment the disease breaks out.

No sudden nor extensive alterations should be made in the usual modes of living. All changes of food, to be useful, indeed not to be absolutely prejudicial, should tend to render it drier, more nutritive and concentrated; moderately costive bowels, the almost invariable consequence of a dry, invigorating diet, will be found more conducive to exemption from cholera than an opposite habit.

Whenever aperients may become indispensable, those of a warm aromatic kind in moderate doses, or domestic means, should alone be resorted to.

What is generally understood by salts, viz. Glauber's salts and Epsom salts, as well as other cold purgatives, should not be taken in any quantities, nor on any account without the express prescription of a medical man.

The medical members of the Board beg to state, in the most decided manner, that no specific preventative against cholera is known to exist, and that the drugs hitherto offered with this pretension, in countries where the greatest ravages have been caused by this disease, not only did not possess the negative virtue of doing no harm, but were found to be absolutely injurious.

The true preventatives are a healthy body,

and a cheerful, unruffled mind. Looseness of bowels should be immediately checked, and any thing like periodical chills or cold perspirations should be met by quinine in suitable doses; but habitual drugging, at all times *improper*, is to be deprecated in the strongest terms, when epidemic disease is apprehended.

The Board has been anxious to lay before the public, as early as possible, the above precautionary outlines, which they trust will tend, together with the suggestions emanating from the wisdom and observation of your and other local Boards, if not to exempt the whole population of these realms from the scourge of spasmodic cholera, at least to enable them to meet it, in the event of its appearing amongst them, with physical and moral constitutions the least likely to suffer from its virulence.

The Central Board will avail themselves of the earliest opportunity to transmit to you any further sanitary suggestions which may occur to them on the subject of precautionary measures, as well as an outline of instructions now in preparation for communities supposed to be actually attacked.

I have the honour to be, Sir,

Your most obedient servant,

E. STEWART, Chairman.

DRS. RUSSELL AND BARRY ON CHOLERA.

THE above named gentlemen, when at Calais, made a memorandum of the conclusions at which they had arrived, on a mature consideration of all they had witnessed abroad relating to Cholera. A copy of this has appeared in various newspapers, but containing several very important mistakes: the source from which we have received that which follows leaves no room to doubt its correctness.

“ After having meditated on the above facts and documents from the moment they came to our knowledge—after having weighed them with all the attention of which our minds are capable, and after having compared the opinions which each of us separately, and without discussion, had grounded upon them, we find our impressions as to the mode of origin and spread of the late epidemic at St. Petersburg and its neighbourhood, so perfectly identical in all important particulars, that we now agree to and sign the following propositions, containing the heads of our unanimous opinions on this part of the business of our mission:—

“ 1. That the germs of the disease were brought to St. Petersburg by the boats and barks which arrived from the interior this year, previously to the 14th (26) of June.

“ 2. That those germs were diffused and the disease propagated in two ways; one

which may be called personal, by the dispersion over the whole city immediately after their arrival, of several thousand passengers and boatmen, who had come from infected places, or had been exposed to infection on the passage or on board these vessels. The other, which may be termed atmospheric, by emanations from the barks, and their contents suspended in and carried by currents of air to susceptible persons, independently of direct communication.

" 3. That the germs of the same disease were carried to Cronstadt, and propagated there by boats and lighters which had been loaded directly from the barks already mentioned, by persons who had recent communication with these barks, or had been in their immediate neighbourhood.

" 4. That the disease was introduced into all the villages round St. Petersburg, in which we have been able to obtain authentic intelligence of its progress, by persons directly from the city, or from other infected places.

" 5. That neither the near approach nor the immediate contact of an infected individual were indispensable to the infection of a healthy individual susceptible of the disease at the moment.

" 6. That the epidemic of St. Petersburg did not possess those absolute and indiscriminating communicable qualities attached to the plague and small-pox, and that the risk of infection incurred by the healthy who approached the sick, was in direct proportion to the want of cleanliness, ventilation, and space, around the latter.

" 7. That in a generally infected atmosphere the additional danger of infection incurred by approaching one or more individuals labouring under this disease was not greater than would accrue from approaching one or more typhus patients under similar circumstances.

" 8. That under favourable circumstances of body and mind, personal seclusion did afford protection against the disease, more particularly if that seclusion had been accompanied by shelter from currents of air passing through sources of infection.

" 9. That those continued exempt from the disease who retired from and avoided communication with infected places; and those who resided to windward of, and those who were protected from the currents of air passing through such places; that the next in point of immunity were those who, though living in the midst of general infection, avoided large accumulations of sick placed in confined atmospheres, the young, the vigorous, those who could afford to live well, yet lived temperately. In short, those who were placed under circumstances the most favourable to health, cheerfulness, and comfort of every kind.

" W. RUSSELL, M.D.

" D. BARRY, M.D."

DEBATE ON CHOLERA.

IN consequence of the very crowded state of the room in Sackville-Street, during the two last nights of meeting of the Westminster Medical Society, the Committee have summoned the members to meet, on Saturday next, in the Great Windmill-Street Museum; when the discussion on cholera will be resumed.

BOOKS RECEIVED FOR REVIEW.

An Essay on the Epidemic Cholera of India. By Reginald Orton, Surgeon, H. P. late of his Majesty's 34th Regiment of Foot. Second Edition, with a Supplement.

Observations on the Nature and Treatment of the Cholera Morbus, now prevailing epidemically in St. Petersburg. By George William Lefevre, M.D.

A Translation of the Eight Books of Aul. Corn. Celsus on Medicine. Second Edition, carefully revised and improved. By G. F. Collier, M.D. of the Academy of Leyden; of Magdalen Hall, Oxford; and of the Royal College of Physicians of London.

A. Cornelii Celsi de Re Medica Libri Octo. Ex recensione Leon. Targæ. Accedunt J. Rhodii, Dissertatio de Celsi Vita, Schillingii Questio de Celsi Ætate, L. Targæ Præfatio et Index Libb. MSS. Editorumque, excerpta de Balneis, de Ponderibus et Mensuris Romanis Monitum breve, cum Conspectu Capitum. Præfixis Characterum, Balnearum, Instrumentorumque Tabulis. Editio Secunda accuratissime emendata opera et studio Georgii Frederici Collier, ex aula Magd. Oxon., e Colleg. Reg. Medic. Lond., et ex Acad. Lugd. Bat. M.D.

ERRATA

In Dr. Elliotson's Lecture, published last week.

P. 169, line 2, after *body* insert *often*.

P. 170, line 23, for *false*, read *fallacious*; same page, line 31, for *minutia*, read *minuteness*.

LECTURES
ON
THE THEORY AND PRACTICE OF
MEDICINE ;

Delivered at the London University,

By DR. ELLIOTSON.

PART I.—LECTURE VIII.

Inflammation(continued.)—Pain—Morbid Appearances—Divisions—Common Inflammation—Symptoms.

IN the last lecture, gentlemen, I commenced the consideration of special pathology—the consideration of particular diseases ; and I stated that I should first speak of those diseases which attack various parts of the body,—that I should then consider such diseases, as seated in particular parts, and consider also those diseases which do not attack various parts, but are confined each to peculiar situations.

I therefore began the consideration of general diseases, if I may so speak ; and, as the most important, the most common, and the most connected with all other affections, I commenced with inflammation. I stated that inflammation was characterized, generally speaking, by four principal signs—redness, swelling, heat, and pain. I considered, as far as appeared necessary, the three first of these ; and, at the conclusion of the lecture, I was speaking of the fourth—namely,

Pain.

I stated that pain, like two of the other symptoms of inflammation, might arise from other causes than inflammation—that is, swelling and heat may exist independently of inflammation, and so may pain. Pain frequently arises from spasm, from scirrhus and cancer, or from neuralgia ; in the latter of which it depends upon a peculiar state of

the nerves, not necessarily inflammatory. But I stated that pain was a very common attendant upon inflammation, though not invariably present.

The pain of inflammation is generally increased by pressure, at least by sudden pressure, whereas pain arising from spasm is generally relieved by pressure. You have this very strikingly shewn in colic and in enteritis. In the latter, the pain, of course, arises from inflammation ; if you press the abdomen, even with the point of one finger, the patient experiences exquisite pain ; whereas, in the former, which is a mere spasm of the intestines, the more you press the more is the patient relieved ; so that I have found a patient able to bear the pressure of both hands, with my feet almost raised from the ground, standing on tiptoe, and the more I pressed the greater was the relief : but the two may be connected, and then you have a certain portion of relief and a certain portion of aggravation.

However, it is necessary to say, that although the pain of inflammation is increased by pressure, it is rather by this being *sudden* than gradually increased ; for frequently, if you press an inflamed part very slightly, and gradually augment the amount, very considerable pressure can be borne, provided you press the *whole* part. If you press only one spot, even slowly, you are sure to give pain ; but if you can embrace the whole part, and press it all gradually, so as to empty it of its blood, you will frequently produce ease. This is shewn every day in the case of inflammation at the bottom of the foot. If you have a blister upon the sole of the foot, or at the ball of the great toe, and you rest gradually upon the part, the pain becomes mitigated, till at last it seems to be almost entirely removed ; but the moment you take off the pressure and raise the foot from the ground, you feel the part begin to throb—to throb with violent pain. It appears, therefore, that if an inflamed part be pressed suddenly it is sure to have its pain increased, if it be pressed even gradually, but only par-

tially, you generally produce the same effect, because, if you press only one part, the other becomes more gorged with blood; but if you can press the whole together, so as gradually to empty all the vessels, or diminish their contents, then pressure can be borne, and, more than that, it frequently gives relief.

Hence pressure has been recommended as a means of cure, by certain writers, in some inflammatory diseases. Pressure has been recommended for the cure of gout and rheumatism, by Dr. Balfour, of Edinburgh; and a French surgeon (Velpeau) has recommended it in erysipelas. But it frequently happens that, although relief may be given in some cases, considerable aggravation is excited in others. It is necessary that the part should be all compressed—that the pressure should be equable; for any deviation in this respect, so that a part of the vessels were allowed to become the more distended, would increase the mischief. Very frequently, too, inflammation does not depend altogether upon local causes; there is a tendency to it in the constitution, and although you impede the circulation of the part, you do not stop the impetus of blood running to it; the large arteries around are found to throb violently against the part compressed, and pressure frequently cannot be borne at all. On all these accounts, it is exceedingly difficult to cure inflammation by pressure. As a general rule, however, we may say that the pain of spasm is diminished by pressure, and the pain of inflammation increased by it; and this criterion is continually resorted to as a means of diagnosis—as a means of distinguishing whether pain is inflammatory or spasmodic.

Pain is, generally speaking, greater in proportion to the tension of the part attacked. The less a part will yield, the greater generally is the pain. Hence much inflammation of a theca of a tendon is generally attended with great agony, and from a similar circumstance, when matter is formed, if it cannot escape, from the part not yielding at all, the pain is most agonizing; whereas, by relieving the tension in making an incision, so as to allow the escape of even the smallest quantity of matter, and the yielding of the part, the pain instantly disappears; and more than that, the great irritation of the system, which, perhaps, amounted to a violent delirium, also vanishes. All these things frequently cease, as it were, by magic, when an incision is made. Hence, too, the great use of incisions in certain inflammations of the skin and the cellular membrane. In what is called *phlegmonous erysipelas*, the cellular membrane becomes excessively gorged with blood—excessively gorged with fluids—the skin is distended, and the greatest agony is felt; but a few incisions will put a stop to all this. I presume it is for the same reason, that, in inflammation of

a serous membrane, you have far more violent pain than in inflammation of a mucous membrane. These serous membranes in general are tense, and give the most violent pain when they are inflamed; whereas the mucous membranes are all of a yielding character, and inflammation of them is consequently never attended by a violent stabbing pain. You know that serous membranes are generally spread out pretty tightly, at least a considerable portion of them, and therefore you generally have a violent stabbing pain when they are inflamed; but sometimes this is not the case, and then the less degree of pain may arise from the affection being seated in a portion that will yield.

But pain, according to its situation in various parts, may be sharp, dull, smarting, or burning. Sometimes it is a mere soreness—no pain is felt unless the part is irritated mechanically, or some particular stimuli are applied. Parts which have little or no sensibility in health, acquire sensibility under inflammation, and frequently very intense sensibility. Many parts which may be cut in health without the individual, be he man or brute, experiencing any sensation, when inflamed cannot bear the slightest motion or the slightest pressure. If, therefore, parts which show no sensibility in health become very sensible in inflammation, you may suppose that parts which are naturally sensible in health may become very painful when in a state of inflammation. However, the degree of pain will not be commensurate with the degree of original sensibility, because it depends so much likewise upon the tension or the yielding character of the part. If it so happen that a part which has no sensibility, or but little, but which is nevertheless an unyielding part, become inflamed, the pain will be dreadful; more dreadful than it would be in a part which naturally has sensibility and yet is of a yielding character.

Diagnosis.—Inflammation is generally known by pain increased on pressure, by feverishness, and a disturbance of the function of the part. When we see a person labouring under disordered function, and labouring under feverishness—pyrexia—and under pain, which pain is increased by pressure, although we cannot see the part, we have no doubt that it is inflamed—that the proximate cause of these symptoms is inflammation. Sometimes there is no pain experienced, but simply disturbance of function and feverishness; and when that is the case, we are not sure that there is an internal inflammation. When a part can be seen, the symptoms which I have already mentioned, few or more of them, will be sufficient to characterize the complaint; but we are certain also of the existence of inflammation when the part is invisible, when we cannot ascertain whether it is red, hot, or swollen or not; but where

there is pain increased on pressure, the function of the part disturbed, and the patient labouring under what is called "feverishness, or pyrexia."

Morbid Appearances.

These are the four symptoms of inflammation during life, but they may have existed at that period and none of them remain after death. The pain and the heat, of course, must go, but the redness and swelling you might expect to remain. When, however, we have seen a part inflamed during life, or such symptoms have been present as to leave no doubt of the existence of inflammation, in both cases you may find, on examination after death, no marks of inflammation at all; and yet the absence of these does not in any way invalidate the opinion which you formed during life; for it will happen that after death every mark of inflammation will disappear. You may sometimes, in inflammation of the surface of the body, or of the eyes, visible enough during life, and of which the patient died, find both parts pale after death; the skin, perhaps, will be slightly swelled, but the swelling will be greatly diminished, and the redness entirely gone. This is a certain fact respecting inflammation in general, because it is observed with regard to external inflammation. After apoplexy you will frequently find nothing. Although during life the head appears to be bursting from an accumulation of blood, and the patient has died of the complaint, yet you will frequently find after death no morbid appearances. All the vessels, when the temperature of the body cools, recover themselves, or the blood in some way or other goes to other parts; but this occurrence does not always take place. You will sometimes find that where there was no doubt from the symptoms that internal inflammation existed, the marks of the complaint disappear after death; sometimes they do, but it is by no means general.

However, on the other hand, you must recollect that it is not every preternatural redness that you discover after death which is inflammatory. You may find an intense redness of the internal parts in the bodies of patients, whom during life you did not suspect to be labouring under inflammation, and you are not on that account *alone* to suppose that they did; for just as the redness of inflammation will frequently disappear after death, either in a great degree or altogether, so after death, without any previous inflammation, you may have morbid redness of the parts. If the patient have died with great difficulty of breathing, so that a large accumulation of blood has taken place in the lungs, you may find the liver gorged with blood, and you may find the mucous membrane of the stomach and intestines exceedingly red, not from inflammation, but simply because the blood

was obstructed in the lungs, or in the heart, and consequently congestion took place. In a case of great debility, a continuance of the patient in one posture during the latter period of his existence will cause such an accumulation of blood as, after death, to give rise to great redness; and these appearances are always greater in proportion to the number of capillary vessels in the part to which the blood inclines by its gravitation. The blood will not merely accumulate in the vessels in this way, but it will transude from them so as to dye the surrounding parts perfectly red, and prevent your distinguishing the appearance from inflammation. This is particularly the case in hot climates and in hot weather. Dr. Davy, the brother of Sir Humphry, says, in a paper published in the tenth volume of the *Medico-Chirurgical Transactions*, that he has found it in hot countries often impossible to distinguish the redness of inflammation from the redness of transudation, or the redness from the circumstance of a piece of membrane being merely steeped in blood; and from all his observations and experiments he draws the conclusion, that if in a hot climate a body be not opened within twenty-four hours after death, the surfaces become red; that the serum of the cavities likewise becomes bloody, and the viscera livid, so that no opinion can be formed as to what was the state of the parts during life. The reason is this—the hotter the temperature within certain limits, the sooner does decomposition take place; the more a part is decomposed, of course the more easily does transudation occur. The solids become more soft, more spongy, and blood which comes in contact with them easily pervades them, oozes through them, and dyes them and any of the liquids which the parts may happen to contain.

You notice in dead bodies which have lain any time upon their back, especially in hot weather, that the posterior parts all become livid, and filled with blood, while the anterior parts are pale. The body being placed usually on the back, if you open it and examine the lungs, you find their posterior part heavy, filled with blood, livid—in fact exhibiting exactly the same appearance as the anterior part does in violent bronchitis; and every one accustomed to make post-mortem examinations allows for this occurrence; he never thinks of considering it a morbid appearance; it is simply the effect of the blood gravitating to the lowest parts. You will observe also when bodies are at all decomposed, that red streaks appear along the surface, in the direction of the various veins. The blood accumulates in all the veins after death, and as the substance of the coats becomes more and more decomposed, it allows the blood contained within the veins to transude, and in that way the coats themselves become thoroughly dyed with blood,

and the cellular membrane around the vessels becomes dyed likewise; you may trace the superficial veins in the dead body from this appearance. This is nothing more than a transudation of the blood, through a degree of decomposition having occurred.

The observations made by Dr. Davy many years ago, respecting the importance of examining bodies early in hot weather, and shewing the importance of knowing that such appearances as are induced by inflammation may take place merely from decomposition, have been all lately confirmed by Andral, who, to make his observations the more striking, has examined the same part of the body at different periods. Early after death he has found an organ pale; but if it were afterwards so placed as to favour the gravitation of the blood to a certain portion of it, that part of the organ, when subsequently examined in a few days, decomposition having proceeded, had become intensely red.

The blood will not only accumulate in the solids in this manner, and not only exude in sufficient quantity to dye any liquids that may be within the cavities, but it will itself exude to such an extent, that a canal may be found containing a large amount of pure blood. By causing a considerable portion of intestine to be dependent, the blood has gravitated to such an extent as to pass through the vessel into the cavity, and there lie in the form of a hemorrhage. Two French writers have made numerous experiments upon this subject, Rigot and Trousseau; and they say that they have frequently made the blood ooze from the inner surface of the intestines, by merely giving a portion of them this dependent position.

You must therefore be aware, that the mere appearance of redness is not sufficient to justify you in saying that a part has been inflamed. A part may be red because it was inflamed during life, but you must always take into consideration, whether the body has lain long, so as to be partly decomposed, and allow the diffusion of blood into the substance of the parts. Indeed, a degree of putrefaction not merely gives this infiltration of blood into the parts, but the parts themselves become dissolved into a liquid substance—they liquify. As the body putrifies it becomes soft, and a large quantity of liquid is produced, in addition to the pure blood, which assists materially in dyeing the different parts. You have therefore to take into consideration what is the period at which you examine the body, and also what is the position of the part, whether it is such as is likely to have favoured the gravitation of its own blood, and that of other parts, in any quantity. You have also to take into consideration another circumstance, independent of time and of position—that is, whether any mechanical obstruction

existed during life. You may examine a body immediately after death, so that putrefaction has not occurred, and placed upon its back with the stomach high, so that the blood could not have gravitated there, and you might see such redness of that organ that you would consider it inflammatory, if you did not also know or ascertain that there had been a mechanical obstruction. If there have been a mechanical obstruction to the return of the blood through the lungs and heart, then that will explain redness of the stomach without your being under the necessity of referring it to inflammation. There are therefore three circumstances to be taken into account—the period at which you examine the body, the situation of the part as to gravitation, and the previous existence or non-existence of mechanical obstruction. A simple inspection of the parts which are red, provided there is nothing but redness, will give you no information whatever. You must ascertain whether there were any symptoms of inflammation during life, and observe the three circumstances to which I have just alluded.

There is, however, another circumstance which will enable you frequently to say that inflammation actually existed, and that is the presence of the products of inflammation. If you find a part intensely red, and you see a layer of lymph effused, or you see a large quantity of serum—perhaps turbid serum—perhaps, too, with flakes, then you may be sure almost that the redness is inflammatory. The redness, it is true, may be increased by decomposition—may be increased by mechanical circumstances; but if you see the products of inflammation, then you may fairly conclude that the redness, either altogether, or the greater part of it, is inflammatory. These observations you will find of use with respect to inflammation in the inner surface of the heart. The lining membrane of the cavity of the heart, especially at the valves, is sometimes very red without any inflammation. Some persons will say there was inflammation during life; others will say that there was not. Of course the point generally may be cleared up by minute observation—by feeling whether the heart is soft or not, so as to allow the membrane to be stained by transuded blood; but if you see an effusion of lymph upon the membrane, then you may be sure that the redness is of an inflammatory character—that it is the result of inflammation, either in part or altogether.

These are the observations that I have thought it necessary to make, gentlemen, respecting the marks of inflammation during life and after death.

Divisions.

Inflammation is usually divided into two kinds—the one *common*, the other *spe-*

cific. "Common" inflammation is that which we see every day where a local injury takes place, or when a part has been exposed to the vicissitudes of temperature; but the epithet, "specific," is given to inflammation when it runs a peculiar course, or when it arises from a peculiar cause, neither mechanical, nor simply irritative. When inflammation runs a peculiar course, it is then by many called "specific," but more frequently it receives that appellation only when it arises from a peculiar cause. For example, inflammation of the urethra, from the forcible introduction of a bougie, or a catheter, would be common inflammation; but the inflammation of gonorrhœa, arising from a peculiar cause, is termed specific inflammation. In specific inflammation you have all the symptoms which occur in common inflammation, but some peculiarity is superadded. Common inflammation is the groundwork, but in specific inflammation some other circumstance is superadded.

Common Inflammation.

I will now speak of the course of common inflammation. Common inflammation may begin with pain, with a blush, and with a feeling of unusual warmth. When an inflammation is first set up, it may begin in this way, but the redness is sometimes not in the form of a blush, but occurs in one particular point, and from that it spreads. If the part be a secreting organ, its secretion will become changed in its appearance—perhaps changed, likewise, in its smell, and at the same time it is generally increased in its quantity. The pain and the redness increase in degree, and also in extent, and then a swelling occurs, or tension, or swelling and tension. The parts swell to a certain point; and if they cannot swell farther without difficulty, they become tense. As the inflammation proceeds, the secretion of the part generally diminishes again, though perhaps it does not come down to, or does not descend below, its natural amount; but the secretions still remain unhealthy in appearance, and, perhaps, also in smell. As all this goes on, or when it arrives at a certain point, the constitution begins to feel its effects. The pulse becomes quickened; and it likewise becomes variously altered in its volume, firmness, strength, and regularity. Thus the constitution sympathizes at last. The affection of the pulse is not always according to the danger; for in mere inflammation of the tonsils, or in mere rheumatism of the joints, both of which are unattended by danger, you will sometimes find the pulse as rapid and as violent, or perhaps more so, than in many dangerous inflammations. The same remark may be made with regard to the temperature. The temperature of the whole body will sometimes be greatly elevated, although the inflammation may be one of no

danger. In a case of mere acute lumbago, from which a man very speedily recovered without any bleeding—merely by the exhibition of colchicum, I found the pulse at 160, and the heat of his whole body 107°. I find, in a note which I made, that he required no blood letting at all, and that he merely took vinum colchici for three or four days, yet that his pulse was 160; and by the thermometer employed by myself, and placed in various parts of the body—under the tongue, and in the axilla, the temperature was not less than 107°. The heat, too, frequently varies in different parts of the body. Besides the alteration of the pulse and the temperature, the patient becomes restless, uneasy in any position, and complains of general soreness; the whole surface of the body frequently becomes sore—the patient feels tender, he says, all over. The head frequently becomes painful, and likewise the loins; and sometimes the pain in these two parts are among the severest constitutional symptoms. The constitutional derangement extends to the secretions, so that most of them become diminished and altered, and from this circumstance you will have, in the first place, thirst. The tongue will be dry or white; and sometimes, if there be much gastric disturbance, it is yellow, or of little strength, dark. The skin becomes dry, though in one particular inflammation—active rheumatism—it generally falls into profuse sweating. The urine becomes scanty; and though it remains clear it is high coloured, and has a strong animal smell—it smells something like gravy soup. The bowels become torpid, and the faces unhealthy, both in colour and smell. These are all instances of diminished or altered secretion.

Now these constitutional symptoms altogether are called by Cullen and his followers *pyrexia*—not fever, but *pyrexia*—fever being the name given by them to certain distinct specific diseases. Some persons denominate these symptoms fever, under all circumstances. We have no English word for this term, *pyrexia*, except we use *feverishness*, but *ish* implies only a slight degree of any thing; whereas the *pyrexia* may be very great, and therefore the term "*pyrexia*" is always better. The word is used by Cullen to distinguish this constitutional excitement under all circumstances, from those specific diseases, which he calls, whether remittent, intermittent, or continued, *fever*; to distinguish it from fever properly so called. However, some persons, aware of the confusion which might arise from calling both these symptoms "*fever*," and other specific fevers, such as typhus, also *fever*, denominate these symptoms when they are dependent upon inflammation, or other local cause—*symptomatic*; and they call the others—fevers, properly so termed—*idiopathic fevers*—fevers

dependent solely upon themselves—grounded by themselves. You will, therefore, find these symptoms, which are sometimes called “constitutional excitement,” “constitutional derangement,” denominated by some writers, “symptomatic fever,” to distinguish them from *real* and specific fever, which they call “idiopathic;” but you find in Cullen the word fever not given to this state in general, but that he uses the word “pyrexia.” For the purposes of clearness, it can make no difference whether, in the case of inflammation, we say pyrexia, or symptomatic fever; for all that is necessary is, that we should make ourselves understood.

Symptoms.

Now it very frequently happens, that when the local disease first begins, before it has increased to such an amount as to quicken the pulse, and induce the other symptoms which I have mentioned, the person complains of chilliness, a general soreness, and even rigors, so that he shivers with cold; the pulse at this time being small, the face pale, and the skin rough—from its deprivation of blood, and its low temperature, it is rough, and is called *goose's skin*—*cutis anserina*, or this state is called *horripilatio*. After the existence of these symptoms—this cold stage, for a certain time—the inflammation appears, and the excitement of the whole constitution gradually begins. Sometimes, therefore, inflammation begins, and after a certain period is attended with constitutional excitement; but sometimes, the moment inflammation begins, the system falls into a cold stage, like fever—exactly such as happens in the cold stage of an intermittent, so that the local inflammation appears simultaneously with the constitutional symptoms.

The general symptoms are usually proportionate to the intensity and the extent of the local inflammation, and likewise to the importance and sympathies of the organ affected; and sometimes, as I have already mentioned, the general symptoms are out of all proportion in their violence, so that if you depended upon them, and did not ascertain the state of the part affected, and recollect its nature, you might suppose the patient was in the greatest danger, when that was not the case. If you found an individual with a temperature of 107° , and a pulse of 160, you would suppose him in imminent peril, if you did not ascertain that the inflammation was inconsiderable, or was seated in a part not at all necessary to life—not at all of importance to the system; whereas, the same derangement attending inflammation of an important organ, or attending a very extensive inflammation of another organ even not so important to life, would point out the greatest danger. You see, therefore, from all I have stated relative to the colour of parts after death, and

the excitement of the system in inflammation, a proof that what I before remarked is well founded, that we are not to depend upon one symptom—one circumstance—in a case, generally speaking, but we must always take into view as many particulars as we can ascertain.

Besides these local and these general symptoms, the functions of the part inflamed are disturbed. This I have already mentioned so far as the secreting organs are affected, but other organs are likewise disturbed. If it be the brain that is inflamed, you have delirium. If it be the lungs that are affected, you have dyspnoea. If it be the stomach, you have vomiting. If it be the intestines, you have either constipation or diarrhoea. If it be the bladder, you of course have a frequent and painful desire to make water.

Buffy Coat.—It is not, however, merely these disturbances—these changes—that take place. The blood itself becomes changed in inflammation. The red particles separate so fully from the fibrin, that this fibrin generally remains colourless and transparent at the top, and, when this occurs, it is said to have a *buffy coat*. There must some change take place in the blood for this phenomenon to occur; and, as soon as you remove a portion of blood from the body, you find that some alteration has taken place, for such are the effects. Occasionally the fibrin, white and clear above from the red particles below, is drawn into such an excavated form, its centre so depressed, that it resembles a cup, and such blood is called *cupped*. Blood may be buffy without being cupped; the red particles may separate entirely from the fibrin, and leave a buffy coat; but sometimes, in addition to this, the fibrin is drawn into an excavated form, so that it is buffed as well as cupped.

Occasionally, this buffy appearance of the blood takes place, it is said, without inflammation. It is usual in pregnancy, but then really a pregnant woman is in an inflammatory state; it is not a state of actual inflammation, but the condition of the womb is really inflammatory. You see that the whole body frequently in pregnancy wastes; the eyes become hollow, and the whole health, for the most part, suffers a little. The pulse becomes very quick—quicker than in health, and all the blood-vessels of the womb become greatly enlarged. The womb itself, if it be not in a state which justifies us in calling it inflammatory, is, nevertheless, in a state of such great activity, that it comes as near to inflammation as possible. And, in truth, with regard to other periods of generation, when animals are in heat, and copulation takes place, the genital organs become violently red, violently hot, perhaps blacken with blood, as if they would burst, and all the blood-vessels around throb. If that state be not to be called inflammation, still it is

very clear that it is all but so, and whatever word you choose to employ, you must look at it as physiologists and pathologists. We cannot therefore wonder, that, in pregnancy, the blood should frequently be buffy.

But this state of the blood is sometimes absent in inflammation. You will find a patient undoubtedly labouring under a most violent inflammation, and on using the remedies for that affection, you produce the most decided effects, and cure him, and yet no buff may be present in the blood. This is by no means uncommon in bronchitis, where a patient has a rapid pulse, great heat of body, cannot turn in bed without coughing, suffers under a difficulty of breathing, so that he is obliged to breathe in a shallow manner; cannot expand the lungs without extreme soreness, tightness, and extreme cough; the tongue is white, and violent pyrexia is present; and if you bleed, you produce instant relief to the patient, so that both the symptoms and the treatment prove the existence of inflammation. The blood will not in bronchitis in many, *many* cases, show the slightest morbid appearance; whereas, if it were another membrane that was inflamed, instead of the lining membrane of the air tubes, as, for instance, the pleura, the smallest quantity of blood that you could take away would most likely show an intensity of buff, and be cupped in addition. The absence of this buffiness of the blood is by no means a proof that there is not inflammation; but, if it be present, it is generally in proportion to the violence of the inflammation. If you be in doubt as to whether the patient is labouring under inflammation or not, the appearance of this buffiness might justify you in concluding, that the symptoms which you suspected to be inflammatory really were so. The absence of it is no proof at all that inflammation does not exist; but the presence of it will, in doubtful cases, very much confirm your conclusions, that the symptoms you were treating were inflammatory. The buffiness, however, is not necessarily in proportion to the *danger* of the inflammation, because in acute rheumatism, where there is no danger whatever—sometimes there is danger in acute rheumatism from internal inflammation, but in a case where there is no danger whatever—the blood will generally be intensely buffed, and not unfrequently intensely cupped at the same time. You are, therefore, usually to consider this as a mark of inflammation, or an inflammatory state; but its absence will not warrant you in saying that there is no inflammation; and the intensity of the buffy or cupped state is not to be considered by you as a proof that the inflammation is of an exceedingly dangerous character*.

ON THE
CEREALIAN ORIGIN
OF
CHOLERA.

By Dr. HAYCRAFT.

It seems rather unaccountable, that amidst the disputes concerning the causes of cholera, that the influence of a vitiated diet, in producing the disease, has not of late years been discussed. Contagion or some peculiar state of the air, or both of them combined, have been assigned as the only probable causes.

That improper diet has been a predisposing cause of cholera in this country as well as in Germany, and also of the epidemic cholera of India, has been allowed by Sydenham, Richter, Sprengel, Rankeen, and many others; and that it usually begins at, or soon after, the harvest period in each country respectively, is also stated by most of these writers. This, added to the consideration that cholera, in its various forms, is essentially a disease affecting the stomach and bowels, and always begins with gastric and splachnic symptoms, would lead us to suppose, that whatever the exciting causes may be, the predisposing cause might consist in the use of food made from corn in its too recent state, or otherwise unfit for the human constitution.

Dr. Rankeen, who was with the army on the Bengal station, in 1818, (see Edin. Med. and Sur. Journ. Jan. 1823,) ascribed the epidemic of the time “chiefly to a diet of rice or other grain vitiated by the wet of the season:” to this Dr. Mason Good, I think without foundation, objects, “that the grain and other food of such wet seasons is usually the product of the year before, which may have been peculiarly dry and healthy.”—(See Study of Med. vol. i. p. 281.) From inquiries I have made of gentlemen well qualified to give an opinion, I find that this objection will not hold good, at least in this country, and probably not in any other. I am informed, that as early as the month of August it is the custom in London to use one part of recent to two parts of old wheat*, and that in some parts of

* In Dr. Elliotson's lecture published in our No. for Nov. 12, p. 173, col. 2, l. 62, for “medicine,” read “médecine.”

* Unless old is mixed with the new wheat, the bread will not “rise,” as it is called, occasioned, I suppose, from the panary fermentation being imperfect.

the country the bread is occasionally made entirely of the most recent wheat, namely, that which a week or ten days previously had been standing in the field. Now this occurs in the month of August, which Sydenham* affirms, and which every body knows, is the month in which cholera in this country is peculiarly rife.

Sprengel† and Richter‡ both accuse a bad quality of diet as a cause of cholera; the latter states, that it prevails in Germany from harvest till August and September, and also that the epidemic cholera of children, in North America, is most frequently about the harvest months.

The Russian cholera of 1829 also made its first appearance in the month of August, or about the harvest period, and according to the statements of Dr. Onufriev, physician for the circle of Orenburg, it appears that during the prevalence of the epidemic, there was scarcely a single inhabitant who had not some symptom of disordered digestion. This was ascribed by some of the physicians to a peculiar epidemic state of the human constitution; others ascribed it to an unusual abundance of fruits, especially of gourds and water melons; but we have too little information on the subject to determine if these universally prevailing symptoms of indigestion were occasioned by some general cause, independent of the state of the air, namely, a vitiated diet. That improper diet, or some general depravity of the usual articles of food, was in fault, is probable; for, we are informed by Dr. Hawkins, in his history of the Epidemic Spasmodic Cholera of Russia, and also by others, that the disease has made its principal ravages among the poorer inhabitants, who "obtain a scanty, and often improper nourishment;" and the Warsaw Committee of Health reports, "that few persons of easy condition have been ill, and that the disease has expended itself chiefly on the poorer inhabitants of that low and thickly peopled city." Indeed, almost all the writers on cholera who have observed the disease, have stated that it attacks chiefly the poorer classes, and those that are badly fed.

The epidemic of 1830 first appeared in June at Rescht, lat. $37^{\circ} 18' N.$ a town in Ghilan, in Persia, situated on the

southern coast of the Caspian Sea: it then appeared at Baku, lat. $40^{\circ} 2' N.$ early in July, and on the 27th July was observed at Teflis, lat. $43^{\circ} 20'$; and about the same time, namely, the 19th July, appeared at Astracan, lat. $46^{\circ} 22' N.$ From Astracan it arrived at Tgaritzza, lat. $48^{\circ} N.$ on the 4th August. On the 6th of the same month it appeared at Saratof, lat. $52^{\circ} 4' N.$; and at Penza, still more to the north, it appeared on the 17th August. "About the end of August" it reached as far north as Nisen or Nischenei-Novogorod, lat. $56^{\circ} 34' N.$; and from this place it branched off in two directions, namely, to the east and by south to Casan, lat. $55^{\circ} 43' 58''$, where it appeared on the 9th September, and also to the west and by south to Moscow, lat. $55^{\circ} 45'$, where it broke out about the same time as at Casan, namely, "about the middle of September."

The reader, if he examine the foregoing paragraph, which I have condensed chiefly from the review of Dr. Lichtenstadt's *Die Asiatische Cholera in Russland*, contained in the *Edin. Med. and Sur. Journ.* July 1831, adding the latitude to each place, will perceive that the date of its first appearance at each place corresponds with the harvest period, which, for the most part, agrees with each respective latitude, with one or two slight exceptions, which may be explained from local circumstances: so that, for example, Casan and Moscow, lying almost exactly in the same latitude, began to be affected almost at the same time, although nearly five hundred miles apart.

The epidemic of 1830 did not cease as did that of the previous year, "but continued to spread with little intermission" westwards, and arrived at Warsaw in the beginning of May. But as it now appears to have assumed a contagious character—on which, however, there are doubts—we should not expect its progress to be distinctly marked by the harvest periods of the different places which it visited. What I would now remark is, that the common diet of the lower classes in the countries which have suffered from the disease, is chiefly bread from rye corn—a species of grain which has always been accused of being more subject than any other to vitiation, both from diseases to which it is liable, such as blight, ergot, &c. as well as to a foreign

* See Opera Universa, p. 177.

† Handbuch der Path. § 123, 127.

‡ Spec. Therap. 4. Band, s. 124.

admixture of injurious seed, such as from *Raphanus raphanistrum*, the *Agrostina*, the *Centaurea cyanus*, the *Nigella sativa*, and the *Lolium temulentum*, all of which the cultivation of rye peculiarly favours. In Georgia, as well as in most parts of European Russia, in the northern parts of Prussia, Poland, and even in Hamburgh, I am informed that the common food of the poor is from rye: often the bread, or rather cakes, are made from grain uncleaned, ground with the husk, imperfectly fermented, and half baked, and in this state kept for use. In Persia, from whence the disease is supposed to be traced, the usual food is rice, the supply of which, we are informed, owing to the improvidence of the people, is seldom sufficient for the supply till the following harvest, so that the inhabitants are obliged to use the new crops in their most recent state. Is it not, therefore, worth inquiring if the propagation of the disease in question is not occasioned, or at least favoured, by an improper quality of diet, especially from *corn bread*, arising from the corn being used in too recent a state, or from a vitiation to which rye is more subject than other grain?

It may, perhaps, assist our inquiries if we turn our attention for a few moments to the epidemic which, at different periods, from the year 1577 to 1771 was so fatal in Silesia, Voightland, Lower Saxony, and other parts in Germany, as well as in Sweden, Switzerland, and in France, between the Cher and the Loire. This disease has, by all writers on the subject, been ascribed to the causes we have mentioned, namely, to an improper quality of bread corn, especially of rye, which was the common food of these countries: it also presents so many resemblances to the epidemic now prevailing in Europe, that a comparison between them will not be uninteresting to the reader. I have, therefore, copied *verbatim* Drs. Barry and Russel's graphic description of the cholera as it occurred at St. Petersburg, and have condensed Richter's description of the epidemic spoken of, which he designates by the name of "Die acute oder fieberhafte Kriebelkrankheit (*raphania* of Mason Good), as contained in his *Specielle Therapie*, vol. vii. p. 607. I have placed each description in alternate paragraphs, that the comparison may be made with greater ease.

Dr. Barry states that "Diarrhœa, at first feculent, with slight cramps in the legs, nausea, pain or heat about the stomach, malaise, give the strongest warning."

According to Richter, the warnings (*vorbothen*) consist in a loss of appetite, furred tongue, pain in the region of the stomach, numbness or slight trembling of the limbs, formication.

"When violent vertigo, sick stomach, nervous agitation, intermittent, slow, and small pulse, cramps beginning at the tip of the fingers and toes, and rapidly approaching the trunk, give the first warnings, there is scarcely an interval."

There is vertigo (*schwindel*), obscure pain in the occiput; pulse small, quick, and intermitting; clonic, alternating with tonic, spasms in some parts.

"Vomiting, purging, or both of these evacuations, of a liquid like rice water or whey, come on."

Vomiting of sometimes nearly black bile. (This dark-coloured vomiting is sometimes observed in the Indian cholera.)

"The features become sharp and contracted, the eye sinks, the look is expressive of terror, and wildness, and as it were, a consciousness on the part of the sufferer that the hand of death is upon him."

The appearance is pale, sunken, and hippocratic; the eyes roll in their sockets, which gives the patient an horrible appearance; he squints, and the pupils are contracted.

"The lips, the face, the hands, the feet, and soon the thighs, arms, and whole surface assume a leaden, blue, purple, black, or deep brown tint, according to the complexion of the individual, varying in shade according to the intensity of the attack. The fingers and toes are reduced at least a third in thickness; the skin, and soft parts covering them, are wrinkled, shrivelled, and folded; the nails put on a blueish pearl white; the larger superficial veins are marked by dark lines, of a deeper black; the pulse is either small as a thread, and scarcely vibrating, or else totally extinct; the skin is deadly cold, and often damp; the tongue is always moist, often white and loaded, but flabby and chilled, like a piece of dead flesh."

The pulse is small, very quick, spasmodic (*krampfhaft*), frequently remitting. The patient has a cold fit (*frost*),

the skin is either rough or dry, or breaks out in a cold clammy sweat, the tongue is always discoloured, and finally almost black. (N.B. In the Indian cholera, the tongue has been observed to have a dark fur towards the end.)

"The voice is nearly gone; the respiration is quick, irregular, and imperfectly performed. Inspiration appears to be effected by an immense effort of the chest, whilst the *aknasi* (in the most hopeless cases, and towards the close), instead of expanding, collapse and stop the ingress of air. Expiration is quick and convulsive. The patient only asks for water, speaks in a plaintive whisper (the *vox cholericæ*), and only by a word at a time, from not being able to retain air in his chest for a sentence."

Respiration is difficult, and performed with great effort, (*heftigen anstrengungen*;) there is, as Mason Good expresses it, "a sense of suffocation, and a difficulty of articulating distinctly," with an unquenchable thirst.

"He tosses incessantly from side to side, and complains of intolerable weight and anguish around the heart. He struggles for breath, and often lays his hand on his stomach and chest, to point out the seat of his agony. The integuments of his belly are sometimes raised into high and irregular folds, whilst the belly itself is violently drawn in, and the diaphragm upwards and inwards towards the chest. Sometimes there are tetanic spasms of the legs, thighs, and loins, but we have not seen tetanus, or even trismus."

The extremities are alternately drawn up and extended, to which is conjoined an irresistible inclination of the patient to restrain these spasmodic movements, in which he succeeds very imperfectly. There is a burning sensation in the internal parts; then follows grinding of the teeth, and even trismus, by which the tongue is not seldom injured.

"There is occasionally a low suffering whine. The secretion of urine is always totally suspended; nor have we observed tears shed under these circumstances. Vomiting and purging, which are far from being the most important or dangerous symptoms, and which in a very great number of cases of the present epidemic have not been profuse, generally cease, or are arrested. . . . Towards the close of the scene the respiration becomes slow; there is a qui-

vering among the tendons of the wrists; the mind remains entire. . . . After the cold blue period has lasted from twelve to twenty-four hours, or upwards, the pulse and external heat begin gradually to return. . . . A profuse critical perspiration comes on from the second to the third day, and leaves the sufferer convalescent; but much more frequently the quickness of pulse and heat of the skin continue; the tongue becomes brown and parched, the eyes are suffused and drowsy; there is a dull flush, with stupor and heaviness, about the countenance, much resembling typhus; dark sordes collect round the lips and teeth; sometimes the patient is pale, squalid, and low, with the pulse and heat below the natural standard,—but with the typhus stupor, delirium supervenes, and death takes place from the fourth to the eighth day, or even later," &c.

Towards the close of the hot stage of the disease the patient falls into a mild delirium, mutters between his teeth, is sad and low, is indifferent to surrounding objects, and neither hears nor sees correctly; he shews all the common symptoms of typhus, *cum torpore, nervosa, stupida*. After some days, colliquative and putrid symptoms set in; meteorismus and emphysematous enlargements, petechiæ, ecchymosis, abscesses and real carbuncles on the extremities, quickly going into mortification. The fingers and toes are first discoloured, and then gangrene; the local mortification soon spreads universally; death happens commonly about the seventh day of the disease.

The reader will perceive two remarkable differences in these diseases, namely, the sense of formication in the extremities at the beginning, and the tendency to mortification of the extremities towards the termination of the disease, which are not observed in cholera. It appears, however, from the authority of Sprengel, Wichmann, and Taube, that these two symptoms belong rather to the chronic raphania; Dr. Mason Good has therefore omitted them in his short sketch of the disease in question, and has with propriety referred the tendency to mortification of the extremities to the chronic disease, under the name of *gangrena urtilaginea*, or mildew mortification, a disease universally ascribed to the same cause as the one before us.

There are many points of resemblance between the two diseases, which we have not yet noticed, namely, the season of the year in which raphania made its appearance—about the harvest period; it also chiefly attacked the poor and ill-fed; it was also remarked that in raphania the violence of the spasms did not indicate the greatest danger; also the most successful treatment was similar, such as large doses of calomel (Taube), antispasmodics, and externally the warm bath, spirituous and stimulating liniments, &c. The post obituary symptoms were also similar, as dark spots on the stomach and intestines, distended with air; the abdominal vessels were found distended with much black carbonized blood (mit vielem schwartzen verkohlten Blute angefüllt). This disease has, notwithstanding its acknowledged cerealian origin, also been supposed to become contagious.

The absence of the congec evacuations, and the presence of bilious vomiting, would induce us to consider the disease as akin to bilious cholera; and the violence of the spasmodic symptoms, among which even trismus has been observed, would give it a nearer resemblance to the spasmodic cholera; the typhoid symptoms, however, would seem to bring it into a nearer relation to the Russian cholera. The chief difference between this disease and the various species of cholera seems to be a less tendency to collapse in its beginning, by which the cold or blue period is less strongly marked; there is likewise a less strikingly observable reaction in the system after the cold stage; also a typhoid character is more observable throughout its whole course.

The chief use I would make of this comparison between the acute raphania, or, as it might be called, the Silesian cholera (from Silesia, where it has been most frequently epidemic), and the other species is, that as that disease has been universally allowed to have had a cerealian origin, it would strengthen our suspicion that the other species may have the same cause.

That diet has some influence in the propagation of epidemics has never been denied; that unwholesome diet prepared from corn in an improper state, especially from rye, which is, as before remarked, more subject than other grain to become unfit for food, has been a frequent cause of fatal epidemics, has

been generally believed. I suspect we may trace somewhat of the acknowledged injurious effect of this kind of diet in modifying the usual bilious cholera of Germany, which, as described by Sprengel, Richter, and other writers, is a much severer disease than we are commonly acquainted with in England, being frequently accompanied by convulsions, and inflammations tending to gangrene, of the stomach and bowels—symptoms that have long since been ascribed to the use of rye food. It may be remarked, likewise, that cholera both in India and Persia, countries whose inhabitants do not cultivate rye, has existed for many years, without exhibiting typhoid symptoms, or being usually supposed to be contagious; yet, as soon as it visited Russia and other rye countries, it puts on a typhoid form, and people begin to believe it to be contagious. I believe also in such countries diseases in general, and especially fevers, do not bear bleeding so well as in this country, and are more apt to run into a typhoid form.

On the whole I am inclined to think, although direct matter-of-fact proofs are not sufficiently numerous to make it certain, that the continental cholera has for its chief predisposing and modifying cause the use of rye as the common diet, and perhaps of that and other grain in a vitiated state; or in other words, that the peculiar epidemic constitution of the human system, by which it becomes predisposed to the Russian cholera, is the said use of rye, immature, or otherwise vitiated.

Should this view be correct, it would be a consolatory reflection that in this country, at least, we shall be exempt from this scourge of the human race, or should it visit us, it will be disarmed of half its terrors.

Even in those instances which have lately been reported, where individuals of the higher ranks, and in whom a vitiated diet may not apparently be accused with justice, yet have received the disease, as is supposed through contagion, such cases, should they be fully proved, would only shew that other causes beside diet would also modify or determine the character of the disease in those individuals: they would not in the least invalidate the idea that the general character of the epidemic has been influenced or determined by the nature of the diet.

I think Dr. Prout's doctrines of *mer-organization* will, when more fully developed, throw much light upon the subject before us: for example, that grain, in its too recent state, may be supposed not to be so perfectly *merorganized* as to be perfectly fit for food. If we consider the *merorganizing* power as something distinct from the organizing, plastic, or formative principle of Sir Gilbert Blane—which latter builds up, as it were, the structure both in vegetable and animal life—it will then be understood to be that which forms or modifies the materials which the organizing power uses in its operations. Merorganization may, then, be considered as a chemico-physiological exposition of digestion, chylication, sanguification, assimilation, secretion, &c.; in all of which, merorganization, we suppose, forms an essential part. Yet, it not only contributes to organization as a preparatory process, but it must also depend upon the latter, because, without organization it could not have place. In grain, when first ripe, the organization, we suppose, is complete; yet we have reason to consider that the greater part of its substance, which is designed for the food of the future plant, as still undergoing the merorganizing process. If we regard the perfection of the panary fermentation as a test of the grain being sufficiently aged to be fit for food, or, in other words, that its *merorganization* is perfect, it would appear that this process requires several months for its performance; for I am informed that the new grain is not fit to be used by itself till about Christmas, until which time it is usual, in London, to mix a considerable proportion of old grain before sending it to the mill*. If grain, then, is used in its too recent state, we suppose that, its merorganization being incomplete, too great a tax is laid on the merorganizing power of the stomach, and probably of the whole system; and this will, if other causes conspire, produce diseases of the stomach and its collatitious viscera; of which diseases cholera is one.

I have also been informed, by good

authority, that the late harvest in this country has not been productive of grain of so good a quality as is commonly believed. Mildew had been unusually prevalent—a disease of corn in which it is observed that a number of grains in each ear are small, and its organization imperfectly developed: how far this may have contributed to the unusual prevalence of cholera after our late harvest, I leave the reader to judge.

The following deductions, then, may be made; but, as we have not all the facts before us necessary for their demonstration, I will merely set them down in the form of queries.

1st. Is it not probable that grain, in its too recent state, or in an otherwise vitiated condition, is a common predisposing cause of cholera?

2dly. That as rye corn is more subject to such vitiation than other grain, and has always been accused of producing disease characterized by its resemblance to Russian cholera; and as the sporadic and epidemic cholera of rye countries have these characters; is it not probable that the use of vitiated rye bread is the predisposing cause of that disease?

It might also form a proper subject for inquiry, how far the various salts used in the manufacture of bread (which salts have been considered as merorganizing substances) may be useful to the human constitution, in preventing a predisposition to cholera; and this inquiry may, perhaps, be made in connexion with the interesting facts mentioned by Dr. Stevens, as well as those communicated through Drs. Barry and Russell, relative to the use of such substances in the treatment of the Russian cholera.

TRANSFUSION OF BLOOD IN CHOLERA, &c.

*To the Editor of the London Medical
Gazette.*

SIR,

As the subject of cholera is becoming daily of more fearful interest, I am sure you will concur with me in the opinion that every suggestion, however remote the benefit of its practical application, demands publicity at the present moment.

* Riechter informs us that the government of the day recommended the inhabitants of the districts most subject to the epidemic, as a prophylactic measure, not to use the rye or barley too new; and also, when thrashed, carefully to separate all other seed, and even to wash and dry the corn in an oven, before sending to the mill, &c.

I offer no further apology for the following hasty observations; and, sir,

I remain, yours, &c.

T. W. W. SMART,

M.R.C.S., &c.

Cranborne, Nov. 14, 1831.

In the first place, I wish to be included within the number of those who object to the appellation of this pestilential disease, which, having been assigned to it on the assumption of a false analogy, is calculated to misdirect us into the paths of mischief and error. Before we may establish the identity of any two diseases, it is essential that the comparison made should be completely accordant in all its parts, neither exclusive of one particular symptom on the one side, nor giving the preference to another on the other side. The history of both must accurately agree. If a partial view alone be taken, we are continually liable to be misled; for how many differing diseases are there not, which manifest symptoms common to all of the same class? For instance, the acute eruptive diseases—in all of them the prefatory febrile affections are alike, and even when the cutaneous inflammation first appears, a mistake is very likely to be made by an unpractised eye, though the more skilful never would confound the early stage of scarlatina with measles, or that of measles with small-pox; for he would apply his power of observation to discover the peculiar diagnostic mark which each wears, in addition to its common resemblance to the other. So is it with English and Asiatic *Cholera*—as it is called. They may have some symptoms in common, but there exist others sufficiently strong to determine a wide distinction between them. Vomiting and purging, the very characteristics of our native disease, are by no means the invariable or most prominent symptoms of the other; spasms, so constant in the Asiatic, are of unfrequent occurrence in *ours*. Then the fatality of the one compared with the almost innocuousness of the other; its decidedly contagious nature; besides, those symptoms of universal paralyzation, that sudden abolition of all physical energy, present to my mind phenomena with which English cholera bears no parallel, not even in degree. It sometimes happens in this country, that

patients under this complaint, (females particularly,) seem very depressed, low, and faint, but not more so, nor so much, as they do often under an attack of hysteria. It frequently happens too, that in some of its severest forms the symptoms of nervous depression are scarcely developed at all. I had an opportunity of remarking this the other day, in one of the most acute cases of cholera I had ever witnessed. It began as usual by rigors, febrile action, pain, vomiting, purging, and the matter voided was of a yeasty pultaceous quality; this was the first stage. The next was ushered in by spasms of the legs, thighs—in fact of the whole frame—accompanied by the most torturing pain; this stage lasted eight hours. Still there was no exhaustion, no debility beyond what one would reasonably expect to ensue after copious evacuation; for I promoted the object of nature to expel the contents of a loaded, stuffed alimentary canal, by the use of purgatives, and they brought away quantities of black, horribly offensive feces. The man was a free liver, a great eater, and he had experienced for two or three days previous to the attack an increasing distention of the abdomen; but when the bowels had been cleared, there was no more distention, no more pain, no more spasm, no more *cholera*,—and this was effected in twenty-four hours; in twenty-four hours more he was well, to his astonishment, considering the previous acute suffering, but still complained of muscular tenderness. This was a specimen—a strong specimen—of English cholera. I might have prescribed the fashionable nostrum, cajeput, in its dose of 40 drops, or preferably to that the oil of turpentine, as it unites the antispasmodic virtue of the former with its own purgative quality; and these remedies might have succeeded *à merveille*; for my idea is, that the cause of the disease is not the presence of acrid bile (*χολη πικρα*), but a spasmodic action of the muscular fibres of the alimentary canal, depending probably on nervous irritation, brought on by the distention, or the excitement produced by an excess or an impurity of the food. But are we to expect success from these, or similar remedies, in the Asiatic pestilence, now threatening to devastate our country—that deathblow of our nature, as it were—that corrupter of the fountain and springs of life? I am incredulous.

lons of the advantage to be derived from their use, as well as from other popular modes of treatment. What, may I ask, are venesection and calomel expected to effect? means, the best adapted, in my opinion, to finally extinguish the still flickering flame of life. When I spoke of cholera as a "corrupter," I meant to allude to the changes which take place in the blood in that disease. This is a fact known to foreign pathologists; it is also known by Clanny and Stevens, that changes, perhaps similar changes, take place in the blood of typhus patients. Hence, there is some reason for assimilating the two diseases, as well as on the additional ground that, after the violence of the attack of cholera is past, fever of a typhoid character is apt to ensue. If the restoration of the healthy properties of the blood be so important a point in the treatment of typhus, as the researches of those gentlemen would affirm, and if this can be effected by the internal administration of carbonic acid gas or the neutral salts, I have long thought, why should not these substances be directly conveyed into the current of circulation by injection? Again, another point of resemblance between the cholera and typhus is seen in that stage of prostration of vital power, which, again, bears some analogy to the prostration resulting from excessive hæmorrhage. I would therefore propose, not only to try the injection of the above remedies into the veins, but also the transfusion of pure blood. The object of treatment seems to me to be that of exciting the vital powers, in fact, of simply keeping the body alive; and would not the substitution of a few ounces of pure blood, in the room of an equal quantity of vitiated fluid, be likely to prove a powerful, as it is the natural, stimulus of the heart's action? I leave these suggestions with your readers, determined myself to act upon them, should circumstances call for my interference. With regard to other plans of treatment, I would mainly rely on brandy and opium, stimulating frictions to the body, stimulating injections, and the hot sand-bath, as it will afford the same advantages as the hot water bath, without incurring the necessity of removing the patient from bed. Steam may be similarly applied.

Note on the late Influenza.

THE influenza visited the part of the country where I reside, in the middle of August, and continued till the latter end of September.

I attended more than 100 cases, but these were not all that occurred.

It attacked persons of all ages, both sexes, of all constitutions, and in all situations. The old, and those weakened by previous diseases, particularly by chronic coughs, felt it most.

It began with the usual symptoms of slow fever, which, in some old people, assumed the typhoid type, and reduced them very low. Then cough, of a spasmodic character, sometimes like whooping-cough, attended with mucous secretion, not affecting the respiratory sound, at least in those cases I subjected to the stethoscope; coryza, epiphora, sore throat; but, whenever it affected the power of deglutition, very little inflammation visible; aphonia, in some cases.

Duration of cases in general about a fortnight.

Only two fatal cases, and those indirectly so. The one, a young girl, who had suffered with spasmodic asthma seven years; the other, an old man, a cripple, with a chronic cough.

In every case, in which my attention to the point after a while was directed, I found tenderness of the spine, chiefly of the upper dorsal and cervical vertebrae, so much, in some instances, that very slight pressure could not be endured; and the intensity of this local affection was in direct ratio with the violence of the general disease. I found antimony, with Dover's powder, the best medicines.

Blisters to the spine relieved the pain in the head and the cough; tartarized antimony ointment irritated.

I consider that the disease was more spasmodic than inflammatory, resulting probably from spinal and other nervous irritation.

T. W. W. SMART.

GALVANISM IN CHOLERA, &c.

To the Editor of the London Medical Gazette.

SIR,

I do not consider a newspaper as the legitimate channel for the conveyance of medical opinions in general, but, under existing circumstances, some allowance should be made for an anxiety

to communicate any information that we may deem important, on the all-engrossing subject of cholera.

Strongly impressed with the conviction that galvanism might be employed, with good effect, in the alarming cold stage of cholera, I addressed a short letter to the editor of the *Globe* and *Traveller*, on Sunday last, (published in that paper on the 15th instant,) with the hope, that the hint might be immediately conveyed to some of my professional brethren at Sunderland.

With your permission, I am desirous of making a few further observations, through the channel of your excellent periodical.

If we may depend upon the experiments, recently made, touching the identity of the "nervous power" and galvanism, as connected with the fact of the evolution of caloric from arterial blood, they may lead to the application of galvanism, for very important remediate purposes, in other diseases, although my present views are principally directed to "spasmodic cholera."

It has fallen to my lot to witness and to treat *very many* of the worst kind of fevers, modified by the different climates of the four quarters of the globe; and it is the conviction of my mind, from all that I have seen and read, that the modified spasmodic cholera, as it has appeared on the continent of Europe, is a fever, only differing in degree, and in a very few symptoms, from some other fevers of a malignant nature.

The poison producing these fevers, (whether arising from malaria, or from the effluvia of the human body,) appears to me to make its primary attack upon the nervous system; and, by its powerful sedative effect, deprives the body of that nervous influence by which only, caloric can be evolved from the arterial blood. Hence the coldness of the body immediately manifested outwardly; and which (coldness) diminishing the capacity of the bloodvessels near the surface, and forcing the blood to retire inwardly, produces that state of congestion of the vital organs so strikingly illustrated by the laboured breathing and languid and oppressed state of the circulation, as well as by the gastric symptoms which generally supervene. The spasms I also attribute to the interruption of the supply of the nervous influence to the different muscles.

With all due deference to those gentlemen who recommend the use of internal stimulants, I must take leave to say, that I think they frequently do much harm. I sincerely believe that the congestive state is rather increased than relieved by giving such quantities of liquid fire.

If I might be permitted to recommend a plan of treatment, I should say, *immediately* on the attack of cholera, place the patient in a warm bed, solicit a return of the circulation to the surface, by means of the hot air-bath, and, if necessary, by passing a gentle and continued stream of galvanism from head to foot of the patient; and then relieve internal congestion by the abstraction of blood from the arm. If the gastric symptoms are severe, I believe that moderate, not large, doses of calomel and opium, frequently repeated, will be found most serviceable in allaying irritation; and even the exhibition of a few drops of prussic acid might be resorted to, in the event of vomiting being a very urgent symptom. The calomel would also have, in the course of a short time, a very beneficial effect, by emulging the liver; for even in the severe cases of English cholera, I have observed that the flow of bile is generally suspended.

It is well known that venesection has been resorted to, with much benefit, in the cold stage of obstinate intermittents. There can be little doubt but that bloodletting relieves, by abating the internal congestion, which had been brought on by the coldness of the surface of the body; but, in these cases, if the hot air-bath were applied at the same time, to solicit a return of the circulation, to the blood-vessels near the surface, the good effect of venesection would be more evident.

On the subject of contagion, I will say but little. I believe the following to be the real state of the matter. When a person, at all predisposed to receive infection, is exposed to the poison of cholera in a concentrated state, he will certainly get the disease; but if not in some measure predisposed to receive infection, he will in all probability escape, even when exposed to the concentrated poison: on the other hand, a person must be strongly predisposed to receive infection, before he can contract the disease, when exposed to the poison in a *diluted* state. Hence arises the

discrepancy of opinion on this subject.

I will close this letter by mentioning an apt illustration of the susceptibility of the same person, at different times and under different states of the body. In the summer of 1801, I had under my care, on board a hospital-ship, in the river Medway, more than a hundred cases of the worst type of typhus fever. For several months I visited these patients three or four times daily, and slept in apartments divided from the sick only by a thin partition of boards, and consequently breathed the hospital atmosphere night and day. Yet, I escaped the fever, although many died around me. One night, however, I unfortunately slept at a friend's house, a few miles distant in the country, and being anxious about a French officer, a prisoner of war, then under my care, I walked from my friend's house, when, heated, and rather tired, I entered the hospital, without resting, or taking my breakfast. I caught the fever, and *narrowly, indeed*, did I escape with my life.—I remain, sir,

Your very obedient servant,
JOHN TWEEDALE, M.D.

Lynn, Norfolk,
Nov. 18, 1831.

APPLICATION OF GALVANISM IN CHOLERA.

To the Editor of the London Medical Gazette.

Lynn-Regis, Norfolk,

SIR,

You can readily imagine that the inhabitants of this place, from their connexion by shipping with the port of Sunderland, are at the present moment in no small degree under the influence of fear of cholera coming amongst them, and that there exists some foundation for this fear no one will deny. The consequences of the panic are, that every individual is putting his house into order; and the magistracy, the head of which possesses energy, and the best of all senses, *common sense*, have to the utmost of their power instituted the wisest precautionary measures, and we are now, as men on the eve of battle, anxious, yet vigilant and prepared.

Of course the medical men at this juncture are not sleeping at their posts, but are cheerfully co-operating, giving their time and thoughts to every measure that is likely to conduce to the health and safety of the inhabitants.

I now address myself to you, for the purpose of eliciting your opinion, and the opinions of the profession generally, through you, (if you deem it worth while) on the probable utility of the application of galvanism in cholera. I have forwarded a letter to the president of the Medical Board in London on the subject, and have no doubt, if the suggestion is of the smallest value, it will meet with attention. I give the following extract from the communication alluded to:—

“The paralyzing effects of the cholera poison upon the viscera of the chest and abdomen, through the medium of the pneumo-gastric and sympathetic nerves, are so abundantly apparent that it has long since struck me (as most probably it has others) that the instantaneously stimulating powers of galvanism may be brought into operation in the stage of deathly collapse, so as to induce reaction, and by giving vigour to the circulation, &c. enable us to pursue a course of practice which the developed disease demands.”

I have not now leisure to proceed further with the subject, but may just mention, that having seen the extraordinary resuscitating powers of galvanism in the case of my own child, who I have every reason to imagine was restored by the influence of galvanism applied for more than twenty minutes along the course of the nerves proceeding to the heart and chest—after being laid lifeless, to all appearance, on its couch from struggling with continued and appalling convulsions for five days, I cannot but entertain a hope that the same means may prove useful in rousing the system out of the overwhelming depression of all its energies, which appears to constitute the most appalling feature and dangerous symptom of cholera.

I have the honour to be, Sir,

Your most obedient servant,
THOMAS INGLE.

CHOLERA—A HINT TO THE LADIES.

—
To the Editor of the London Medical Gazette.

SIR,

AT a time like this, when every mind is agitated by direful apprehension of the awful plague which, having ravaged so large a portion of the continent, has at length reached our shores, no suggestions, however apparently trifling, can, I trust, be deemed really unimportant if they tend, in any degree, to promote precautionary measures, especially, too, when those suggestions are addressed to the "better half of man," and may possibly guard them from much danger. I would, therefore, through the medium of your highly-valuable and intelligent journal, earnestly call their attention to the few following observations, and beseech them to put them into practice, since, as they cannot at all events be injurious, they may be eminently beneficial. First, then, I would strongly recommend them to pay particular and constant attention to the preservation of warmth, which is universally acknowledged to be one of the most efficient means of prevention. With this view, they must, of course, give strict attention to their clothing, selecting such articles of dress as are of the warmest texture, without so much regard to appearances as too generally prevails, and especially keeping warmly covered the neck, bosom, feet, and arms—parts of the body the chilling of which occasions often the most lamentable results. I would advise them to discard the thin and flimsy silk stockings which are so much worn, and adopt woollen ones, with boots; for cold feet in an eminent degree contribute to produce severe affections of those very organs most concerned in cholera. What are called snow-boots, also, would be very useful and comfortable for exercising in, both in carriages and when walking: they may not be very elegant; but surely that should be no consideration when the preservation of life is put in competition. Next I would advise them to avoid the practice of tight-lacing, than which nothing can at any time be more injurious, but now of the most vital necessity; for only let them consider the importance of the organs which are compressed and squeezed out of all natural

shape and proportion by such a habit; and let them be informed that two of these—the lungs—are great outlets to carry off any deleterious matter in the system, which function they cannot perform if their size is diminished, and their action hindered by the forcible compression of the chest, occasioned by tight stays.

Next, I would most seriously urge upon them not to frequent large, crowded, and heated parties and assemblies, where they are compelled to breathe over and over again the contaminated atmosphere created by the congregation of many persons, and where also they are more subject to the effects of cold air: when quitting the heated and crowded room they have often, in winter, to encounter a cutting, frosty wind, and perhaps sleet or snow, in entering their carriages. In addition to the foregoing advice, I would also recommend those of a nervous temperament, and those with languid circulation, to have the limbs and surface of the body well rubbed every morning and evening, for at least half an hour each time, so as to excite a healthy action of the nerves and blood-vessels, and regularly to take exercise by walking in the open air for two hours at least daily, and to observe regular and earlier hours for their meals than are now the fashion. And last, though not least, let them, putting a firm trust in that Almighty power which can alone direct and stay this plague, discard as much as possible unnecessary fear, and employ themselves in cheerful occupations, with which domestic affairs will supply them; and in a blessed way may their minds be further preserved from personal apprehension by their preparing, as far as is in their power, articles of clothing, and other comforts, to distribute among their poorer fellow-creatures, who, if attacked by this horrible malady, will in this manner be better provided to withstand its effects, and whose blessings will carry joy and peace to their hearts. If, sir, these few suggestions should be thought by you worthy of insertion, you will much oblige one who is anxious for the welfare of the fair sex, and who begs leave to remain your obedient servant,

PHILOGYNAIKOS.

Nov. 15th, 1831.

A BRIEF SKETCH
OF
THE BOTANY OF THE VICINITY OF
SYDNEY, NEW SOUTH WALES.

BY GEORGE BENNETT.

HAVING arrived at this interesting colony on the 22d of January, 1829, my attention was soon directed towards its numerous vegetable productions; but my brief sojourn did not permit any extension of my *herborizations* far inland. The Botanic Garden, however, established at Sydney (under the superintendence of Mr. Frazer), afforded me ample opportunities of viewing the more distant indigenous productions of the colony.

The country in the vicinity of Sydney was strewed with a profusion of flowering shrubs, thriving in an arid soil; but there seemed to be a peculiar character in the vegetation of this country, the foliage of the Australian trees and shrubs having a dry appearance, and being destitute of that lustre so observable usually in those of other countries. This want of lustre is attributed, by Mr. Brown, to the equal existence of cutaneous glands on both surfaces of the leaf*. Another peculiarity is the lofty trees being destitute of branches, excepting at the summits, and shedding their bark; some being observed perfectly decorticated, and in others the cortex is seen hanging in long strips about the trunk. All these peculiarities conveying to us different ideas from those which had been formed from the vegetation of other countries.

Among the extensive Proteaceæ family was the *Grevillea sericea*, *Isopogon anethifolius*, &c. and the beautiful *Banksia* genus (the honeysuckle of the colonists)†, the wood of which is used

by the colonists for boat-building: among numerous species of this genus was the *spinosa*, *serrata*, *integrifolia*, *ericæfolia*, &c. The *Hakea* genus was also abundant. That curious tree of the *Asphodelæ* family, the *Xanthorrhæa*, or yellow gum-tree, attracted observation by its peculiar growth, long grassy foliage (from which it derives its name of grass-tree from the colonists), and towering scape, terminating in a cylindrical spike, either crowded with its small white melliferous flowers or dark-coloured angulated capsules, containing small black seeds.

At a beautiful glen at Little Cudjee, near the south head of Port Jackson, among other plants I collected the *Smilax glycyphylla*, or sweet tea-plant of the colonists, which was, on the first establishment of the colony, extensively used instead of the "China shrub." It is a scandent plant, and the leaves have a sweetish taste, resembling that of liquorice-root, which afterwards leaves a very slight bitter. Among the ferns collected were the *Davallia elegans*, *Gleichenia microphylla*, *Polypodium attenuatum* (Brown Prod. Nov. Holl.), and others. In the vales were found that elegant Proteaceous shrub the *Warratah*, or tulip-tree, *Telopea speciosissima*, and the *Xylomelum pyrifforme* (Proteaceæ), or native pear-tree, so named from its pyriform fruit.

In the Botanic Garden, the species of *Acacia* indigenous to Australia were very numerous; among them was the *A. stenophylla*, from the south-west interior, and was the only tree seen on the horizon at the *ne plus ultra* of Oxley's expedition of 1817, at the termination of the River Lachlan; the *A. fillifanilius*, from the deserts of the south-west interior (vide Oxley's Expedition, 1817); *A. floribunda*, *pubescens*, *falcata**, &c. &c. The magnificent Norfolk Island pine (*Araucaria excelsa*) also grows in the garden as well as at other parts of the colony, where it forms an adornment to the avenues, &c.

The olive trees thrive well in the colony, and attain, it is said, a greater size in a shorter period of time, than even in their native country. Young plants are propagated by layers, and are given to such of the settlers as are desirous of raising this valuable shrub. The *Casuarina palludosa*, *Hibiscus spec-*

* "It is at least certain that on this microscopic character of the equal existence of cutaneous glands on both surfaces of the leaf, depends that want of lustre which is so remarkable in the forests of New Holland."—*Sketch of the Botany of the Vicinity of Swan River*, by R. Brown, Esq. F.R.S. published in the Journal of the Royal Geographical Society of London, 1830-31.

† "When the different species of *Banksia* first come into bloom, the natives collect from the flowers a considerable quantity of honey, of which they are particularly fond, and gather large quantities of the flowers (*moncat*) to suck. It is not, however, always to be procured: the best time is in the morning, when much dew is deposited on the ground; also in cloudy, but not wet weather."—*Description of the Natives of King George's Sound (Swan River Colony) and adjoining Country*, by Mr. Scott Hind, published in the Journal of the Royal Geographical Society of London, 1830-31, p. 35.

* This species is found very abundant at most of the Polynesian Islands.

tabilis, and several new plants and shrubs from Moreton Bay, with a collection too extensive to enumerate, sufficiently engages the attention of the visitors to this garden. The castor oil tree (*Ricinus communis*) abounds almost in a wild state, and yet the oil is still imported into the colony, when any quantity that may be required could be expressed, not only for medicinal purposes, but for burning in the lamps, for which latter purpose it is used in some parts of South America.

On the 13th of February (1829), I visited Botany Bay, and collected numerous botanical specimens. Among several of the *Encalyptus* genus was observed the *E. resinifera*, or red gum tree, *E. corymbosa*, &c. The leaves of most of this genus have a peculiar smell when broken, somewhat resembling the cajuput oil; there is one species in the botanic garden which had been brought from the interior, the leaves of which yielded a quantity of oil resembling the cajuput; on breaking a leaf in the hand, the oil which exuded was very abundant. During this *herborization* I collected among others the following plants:—

<i>Burronia polygalafolia</i> .	<i>Oxalis Australis</i> .
<i>Leptospermum Juniperina</i> .	<i>Epacris microphylla</i> .
<i>Melaleuca Fimbriata</i> .	<i>Exocarpus cupressiforme</i> .
<i>Metrosideros lancifolia</i> .	<i>Sympheonia montana</i> .
<i>Viminaria juncea</i> .	<i>Liptomera acida</i> .
<i>Epacris palludosa</i> .	<i>Enokelia major et minor</i> .
<i>Calytus Australis</i> .	<i>Lobelia gracilis</i> .
<i>Hibbertia volubilis</i> .	<i>Lambertia formosa</i> .
<i>Blandfordia nobilis</i> .	&c. &c. &c.

Botany, as well as other branches of natural history, has an extensive range in Australasia; the discoveries made have been very numerous; and when it is considered that an immense extent of land still remains unexplored, many treasures in natural history may yet be looked for from that new and extraordinary portion of the globe.

London, Nov. 12, 1831.

REMARKS ON SOME REMEDIES IN THE TREATMENT OF INSANITY.

To the Editor of the London Medical Gazette.

SIR,

It appears to me, upon perusing the report of Dr. Seymour's Croonian lecture on the medical treatment of Insanity, in

the Medical Gazette of October 29th, that some errors must have occurred in the abridging of it, which render the lecturer's meaning obscure; nay, perhaps, pervert it.*

Dr. Seymour is therein reported to advise "blood-letting, principally from the jugular vein, if on accurate inquiry the patient has been exposed to causes sufficient to produce inflammation of the brain, redness of the countenance, &c." because such symptoms "point out increased vascular action, with increased power." A case is cited to prove the good effects of this practice; but no symptoms are described indicative of cerebral inflammation, though many of mental derangement. As Dr. S. subsequently cautions against general blood-letting in cases of insanity, I think it is clear he never would prescribe it because a patient had merely been exposed to sufficient cause to produce inflammation of the brain, for he has too much experience and judgment not to know that exposure to the same causes may produce either acute inflammation, or simple derangement of the faculties of the mind.

I am the more anxious that the doctor should be clearly understood on this subject; for having very fully discussed the effects of abstractions of blood in the cure of insanity†, and knowing that medical practitioners are beginning to be aware of the danger of copious resection in such cases, misconception might occasion a relapse into former errors.

Again, there is another passage which strikes me as a misinterpretation.

Dr. S. is reported to say, that physicians, "in seeking for means to allay the inordinately increased sensibility, principally, of course, occurring in that division of insanity termed *dementia*," should commence with the application of cold, in the form of ice, the shower-bath, or in a descending column of water, termed the "douche," not only to diminish vascular excitement, but as having a really sedative effect.

I fully appreciate the beneficial effects of refrigeration in a high state of vascular excitement, and the sedative powers, when the brain is the seat of excitation from that cause. *Si calor, aqua frigida multa perfundere caput*

* The circumstances under which the paper was published, render it impossible that this should have been the case.—ED. GAZ.

† Commentaries on Insanity, pp. 533-533.

expedit, is a Celsian axiom never to be forgotten in the cure of insanity. But it should be noted, that this form of the malady (dementia) is rarely accompanied by vascular excitement, and inordinately increased sensibility.

Dementia is considered by Esquirol, and others, to be owing either to the sensitive organs becoming weakened, or because the brain itself has not sufficient powers to receive and retain the impression which is transmitted to it. In fact, it implies that the energy of the brain is impaired, and therefore demands remedies, not to allay, but to stimulate and strengthen its energies,

There is, however, an acute form of dementia, attended occasionally by symptoms of vascular and cerebral excitation; and, during the existence of those symptoms, and only then, local sedative applications to the head are indicated. It is to this form of dementia solely that, I have no doubt, Dr. Seymour refers.

But the "douche," once so infallible, and so great a favourite with French physicians in the treatment of insanity, like most extravagantly vaunted remedies, has had its day, and is now comparatively little used as a means of cure. When resorted to, it is more as a means of repression, and a moral agent in furious cases. Death, disorganization of the brain, and incurability, has been not unfrequently the result of its application. As a remedy, it is now actually proscribed, in many of the best-conducted continental lunatic asylums, as absolutely dangerous. In British asylums, objections have always been made to the use of the douche.

The case quoted by Dr. S. (p. 113) is an excellent illustration of the good effects of the shower-bath in *furious mania*; but your reporter, Mr. Editor, has, no doubt erroneously, made the learned lecturer conclude, that, from the statement in that case, "it is to cases of *dementia* that it is applicable."

In a malady so obnoxious to remedies as insanity, every one suggested by respectable authority should have a fair trial. On Dr. Jenner's recommendation principally, I gave an ample trial to the inunction of tartarized antimony, as a counter-irritant. My success was by no means commensurate with the expectations raised by his account of its good effects in maniacal cases. The only cases wherein I found it useful

were when accustomed cutaneous eruptions had omitted to appear, or when they had suddenly receded, or when there had been, previously to the maniacal attack, great gastric irritation.

Dr. Jenner's formula* for this remedy is the best, because the most expeditious in its effects on the skin. If counter-irritation be the sole object of blistering in mania, the tartarized antimony is very much to be preferred to cantharides. Vesication, by the application of the latter, especially if there exists much vascular excitement, commonly increases violence, and often superadds the irritation of strangury. From the pustular eruptions of the former, such consequences are not to be apprehended.

In respect to the effects of narcotics, especially of opium, in cases of insanity, about which so great discrepancy prevails, I shall take the liberty of offering a few observations, by way of explanation. Having very fully treated on this subject elsewhere, I will be here as brief as possible†.

I suspect that the discrepancies concerning the effects of narcotics, in the treatment of insanity, have arisen from ignorance, or disregard of the distinct stages which this malady assumes.

Mania, certainly, comes on sometimes very suddenly; but commonly there are three distinct stages observable—1, incipient; 2, active; 3, decline. In each of these stages the symptoms differ in form or intensity, and in each the exhibition of a narcotic, particularly of opium, will produce different effects.

The good, or ill, or no effect of an opiate, is chiefly regulated by the observance or omission of having previously removed cerebral congestion and excitement, by local abstraction of blood from the scalp, and by emptying the primæ viæ. Unless evacuation be premised, sleep may sometimes be enforced by an opiate, but the degree of excitation will assuredly be aggravated.

Dr. S. is misinformed in stating that that powerful sedative, hydrocyanic acid, had not been prescribed in this country in the treatment of insanity.

During a tour I made of the public lunatic asylums in Great Britain, in the years 1821 and 1822, I learnt that very full trials had been made of its effects in

* Supra cit. p. 623.

† Ibid. pp. 610-618.

several of them. As of all other remedies, its effects were differently represented. Some practitioners had abandoned it as inefficient; others thought it had been beneficial in a few cases; others again had a high opinion of its antimanical powers.

The physician who, I believe, has given it the longest and most extensive trial, is my friend Dr. Balmanno, of the Glasgow Lunatic Asylum. I have adverted to his experience of the effects of prussic acid in my work on Insanity, and the result of my trial of its virtues on the recommendation of this experienced physician*. It is candid to confess, that mine was not a fair trial of its virtues; for, knowing its active and dangerous properties, I was unwilling to entrust its exhibition to any one but myself, and as I could not always be present to see it administered with due regularity, I did not persist with it.

In answer to an inquiry I made of Dr. Balmanno in 1828, whether he continued to exhibit this preparation, he says, "I still use the prussic acid, and generally in combination with hyosciamus. The formula is the following:—

R Extracti Hyosciami, ℥j.
Syrupi Sacchari, ℥xij. Misce.

"This is 5ij. of the extract to ℥j. of the syrup. Of this syrup I never give less than 3ij. for a dose, commonly with gtt. xxx. of the prussic acid. When this does not procure rest or quietness, I increase the dose; and I increased it in one case to an ounce and a half of the syrup, and eighty drops of the prussic acid, for one dose, with complete effect. In short, I never fail to quiet the most highly-excited maniac by this medium. Generally, throughout the day following a sufficient dose, the patient is calm, or somewhat stupid. I never saw the smallest injury produced by the largest dose I have given."

Aware of the fatal result attending in Dr. Ferrus's cases at the Bicêtre, in Paris, from the hydrocyanic acid being administered prepared from a different formula to that which he had been accustomed to prescribe, I requested Dr. Balmanno to inform me what preparation of it he made use of. In a letter I received from him last year, he observes, "I have not yet slain any of my patients by the prussic acid; but I still give the

medicine with the hyoscyamus; and both in mania, and in the delirium of typhus fever, I find the combination effectual. The prussic acid which I use is that which is commonly procured from the shops."

In respect to arsenic, the utility of which Dr. Seymour suggests in maniacal cases, and which he believes has not been tried, I may remark that it has been recommended by several British authors in chronic insanity assuming a decidedly periodical type; and in Germany especially, and in other countries of Europe, arsenic has been most extensively used with the same intention.

Having before fully commented on the other remedies discussed by Dr. S. in the work referred to, I shall not lengthen this letter by a repetition of my remarks. Several, however, are omitted, such as digitalis, gyration, and the swing, highly deserving notice in a review of the remedies applicable to the medical treatment of insanity.

I am, Sir,

Your obedient servant,

G. MANN BURROWS.

64, Great Russell-Street, Bloomsbury-Square,
November 1831.

CASE OF PROLAPSUS UTERI,

Cured by a New Operation.

BY MARSHALL HALL, M.D. F.R.S.E. &c.

THE subject of the case which I am about to detail, was a poor woman, whose bread depended upon the labour of her hands. Her sufferings, from the prolapsed state of the uterus, were often extreme, and she was frequently disabled from engaging in her various occupations.

For several years there had been complete prolapsus of the uterus; to this were also conjoined a partial descent of the bladder at the anterior, and of the rectum, formed into a pouch, at the posterior part of this prolapsus. The os uteri protruded at least two inches beyond the os externum.

It occurred to me that, if the canal of the vagina could be considerably, permanently, and firmly, reduced in its diameter, the uterus would be supported

* Supra cit. p. 656.

in its place, and prevented from resuming its prolapsed situation; and that this might be done by removing a portion of its mucous membrane along the anterior part, and by bringing and returning the denuded surfaces in contact by successive deep sutures, until they should unite by cicatrix.

This operation was performed by Mr. Heming, of Kentish Town. The uterus being protruded as much as possible, by the efforts of the patient, two parallel incisions were made through the mucous membrane, from the sides of the os uteri, along the course of the protruded vagina, to the os externum; the portion of this membrane situated between these incisions was then removed, leaving a space of one inch and a half in breadth, and of the entire length of the vagina, completely denuded. A suture was then inserted, near the os uteri. This suture being tightened, the os uteri was obviously pushed upwards. A second, a third, and other ligatures, were then inserted, in the same manner, at short intervals, to the os externum; each ligature, on being tightened, moving and supporting the os uteri upwards.

This operation was attended with little pain; the only sensitive parts of the membrane being those near the os uteri and os externum.

The patient was directed to keep quiet in bed. The bowels had been opened. An opiate was given. No pain or fever followed. In four or five weeks the denuded parts had firmly united, and shortly afterwards the ligatures were come away.

On examination, six, eight, and ten weeks after the operation, the os uteri could be just felt *in situ*, by the finger passed through the vagina: the vagina was firmly contracted along its whole course.

The prolapsus of the uterus was thus completely remedied. The descent of the pouch of the rectum was lessened.

14, Manchester-Square,
Nov. 19, 1831.

P. S. The principle upon which this case was treated, is illustrated by a fact, detailed to me by Dr. Holland, of Queen-Street, May-Fair. A pessary, introduced in a young person to support the uterus, subject to be completely prolapsed, induced great inflammation. This was followed by such firm contraction of the vagina, that the uterus ever

afterwards remained in its proper situation.

MEDICAL GAZETTE.

Saturday, November 26, 1831.

"Licet omnibus, licet etiam mihi, dignitatem *Ar-
tis Medicæ* lueri; potestas modo veniendi in pub-
licum sit, dicendi periculum non recuso."—CICERO.

THE "BURKING" SYSTEM.

THE fearful disclosures made within the last week or two, through the activity of our excellent police, have thoroughly and justly alarmed the public mind. The cry of "burking" is once more revived; and, candidly speaking, (apart from the horror which we entertain in common with the rest of society for this worse than cannibal crime,) we are not sorry that it is revived. The existence of such a state of things in any community, as that wretches should be induced, under any circumstances, to murder the living for the sake of the profits arising from the sale of the dead, is dreadful; but if it does exist, it is undoubtedly better it should be known—else will the said community for ever remain obstinately bent upon avoiding the only reasonable measures for its prevention.

The preventive remedy is no secret—yet its use, we see, is constantly declined, because, forsooth, some say, it would interfere with certain supposed sympathies of persons unknown, or rather perhaps (if the truth were more honestly told) because it would prove to be productive of inconvenience to an influential class of individuals interested; and all this, while the evil to be remedied—especially in its recent hideous shape, is held to be of uncommonly rare occurrence.

We really believe that many were beginning to think of the Edinburgh atrocities as a species of horror unique and *sui generis*, and that its foul perpetrator was a monster such as the world never saw before, nor were

likely ever to see again: certain it is, that vivid impressions of this "deed without a name" (until one was given it after the arch criminal) were fast wearing out, and that many recurred to the facts almost as they would to some harrowing spectacle which they had witnessed on the mimic stage, rather than on that of real life. From time to time a faint alarm would be raised of the existence of similar criminality here and there through the country; but the rumours were ill-defined, and such frequently, as upon being discovered to be destitute of foundation, served but for merriment; until a period at length elapsed (however short) sufficient to tranquillize every apprehension about the reappearance of similar guilt, and to render people unprepared for a second revealment of "burking." This false security is now disturbed—the film is removed from the eyes of the short-sighted—and they are painfully awakened to the dread possibility of this horrible crime going on within the very range of their daily walks. We are sorry we cannot condole with them: we do not on this question belong to the party of the tender-hearted incredulous, but to our shame, (if they will have it so) be it spoken, we confess ourselves to be rather content with the disclosures which have been made, and strongly inclined to congratulate the public upon them. As to surprise—we are sorry to say that it is an occasion on which we can feel none.

Truth to speak, whatever may have been our surmises before, we never had the slightest doubt since the revolting confessions in Edinburgh, of the more than possible existence of the same system in London. This great capital, we thought, was too notorious as the Babylonian nursing-mother of every vice under heaven—too full of a progeny ingenious in every branch of iniquity, not to possess at least a reasonable number of adepts deep in the mys-

teries of the new crime, if mystery there can be said to be in any thing about "burking," except in the concealment. We scarcely wanted a Gibbon Wakefield to warn us of our danger; though the recent pamphlet of that writer appears most opportunely to confirm our view of the circumstances, and to convince all good citizens of the desperate gangs of wretches who hover around them every hour—ruffians, rabble, and desperadoes, capable and ready for the commission of any enormity. We were satisfied with what we knew of the habits and capabilities of one set of miscreants tolerated in the community—we had the resurrection-men before our eyes. Far be it from us, however, to raise a single prejudice against the individuals of that class who await their trial at the Old Bailey: we only speak of the class abstractedly, as the most obviously chargeable with a crime like that for which those individuals will be arraigned. Let us take a single human being of that order—one who has fallen, from whatever cause, into that lowest of all vocations, the business of a resurrection-man. His employment is a secret, or known but to a few ill-trusted wretches of his own condition; it suffices not, with all its dangers, for his maintenance; he cannot live by it alone; he becomes a thief—that is, if he have courage enough to raise himself a degree above the abominations of body-snatching; the instruments for grave-breaking are also those for house-breaking, and the same vehicle which is used for removing the contents of the grave serves also for conveying away stolen goods*. This, however, is the picture of a resurrection-man not quite destitute of the humanities—one not yet deadened to the impulses of a sort of stealthy industry, and willing to save himself from the shifts of the lowest and most brutal de-

* See the evidence of the resurrection-men, A. B. and C. D., in the Parliamentary Report of the Committee of Anatomy, 1828.

gradation. But we can conceive another wretch, capable of adding one crime more to the catalogue of his iniquities. He sees before him the prospect of a prize, far more promising than the amount of nine out of ten of the robberies which he might have it in his power to commit; he has within his grasp the fruits without the risks of body-snatching; the temptation from the high premium in view is irresistible, even though the facility of concealment were infinitely less. Now comes the victim in his way—some solitary wanderer, helpless, or rendered so by the stupor of intoxication:—the deed is done!—the murderer is familiar with the appearances of death—he hampers up his *subject*, and hastens for the possession of the lucre which he has earned. The entire order of these miscreants must be abolished: the wretches who live by the spoliation of the grave—much less those who add murder to that offence—must not pollute society with their presence.

But the preventive remedy, as we have said, is no secret. Amend the laws as they affect the practice of dissection—if not for the safety of the public, at least for the preservation of our national character as regards our legislative arrangements. Foreigners should no longer be permitted to observe, that British law is in one part so dangerously absurd, as to ordain that certain of its enactments can only be complied with by a violation of other of its ordinances. Yet so it is; and these are the very enactments and ordinances which profess to regulate our profession, and have at length given rise to a species of crime unknown to former ages, and startling to the contemporaries of this. The time is come when it is imperative on the legislature to interfere: the laws *must* be amended—some provision *must* be made for dissection, *or the practice of anatomy must be prohibited altogether*:

there is no alternative. This point, however, is so clearly expressed in a very sensible letter which appeared in a late number of the *Times*, that we cannot deny ourselves the pleasure of a short extract from it by way of conclusion.

“While such a traffic exists, there can be no security for the public. The legislature of the country can no longer turn a deaf ear to the voice which has so often warned them on the subject. They must interfere in one or other of two ways:—either they must prohibit the teaching of anatomy altogether, and allow medical and surgical science to go back in the next generation to what it was some centuries ago; or they must remove those obstructions which the common law of the land (as it is construed by the judges) has imposed on the study of anatomy by dissection. My firm conviction is, that the latter alternative is completely within their power: that by some very simple enactments the schools of anatomy may be supplied with subjects, without the smallest offence to public decency, without the smallest outrage on the feelings of individuals, and without any danger to human life. No one who will be at the pains to peruse the report of the Anatomical Committee of the House of Commons, and at the same time to make himself acquainted with what is done in France, Italy, Germany, and even in some of the United States of America, can, as I conceive, entertain a doubt as to this opinion being correct.

“If, however, those in whose department it is to make the laws by which we are governed, come to a different conclusion, let them at once and altogether prohibit anatomical instruction. The medical profession, that is, we who are now established in practice, cannot complain that our interests are in any way compromised if they do so. On the contrary, we shall thereby obtain all the advantages of a monopoly. We may then, if we are so disposed, contrive to exercise our art even in our dotage, for there will be no succession of younger and well-educated competitors to push us from our stools. The children and grandchildren of those who now exist, may suffer for the want of medical and surgical assistance, when they sink under the depressing influence

or writhe under the tortures of disease ; but to us, the existing race of medical practitioners, if we were selfish, we could wish for no better consummation than this*."

CHOLERA AT SUNDERLAND.

THE good people of Sunderland really appear in no very favourable light. It seems pretty clear that the public safety is, in their estimation, a very secondary object when brought into competition with the sale of coals. We last week stated our opinion, founded on the evidence of the returns, that the whole truth was not made known ; and Dr. Daun's letter, which has since been published, confirms the accuracy of our suspicions. Upon his representation, and that of Dr. Barry, it is to be presumed that the Privy Council issued the order which appeared a few days ago, by which medical men were every where enjoined to report their cases instantly, under certain pains and penalties. Many of our brethren have an idea that the law does not bear out the imperative tone of the mandate ; but in this they deceive themselves. A reference to the quarantine act will shew that practitioners must obey, or expose themselves to summary punishment. Medical men cannot, however, be compelled to give their services gratuitously ; and the proclamation alluded to will probably make them more chary in doing so ; indeed, we do not see why the *doctor* should be the only professional man whose services are expected to be had for the asking, and quite as a matter of course. Regarding cholera as a contagious disease, we would suggest that an adequate number of medical men should be appointed in each district, to take charge of the sick, and that their practice for the time should be limited to that disease, otherwise how are the public ever to be safe against the constantly renewed dissemination of so diffusible a poison?—

Medical advice, too, though rendered accessible, ought not to be forced upon the poor, else we shall have them accusing the doctors of poisoning them, and then murdering their attendants, in return for their services, as they did by wholesale in several parts of Russia.

As to Sunderland, no doubt is entertained of the disease which prevails there being the same as that which has been the scourge of India and the north of Europe. This has been decided by those who have seen both. We are still left without any official details, either of the symptoms or of the treatment ; but from our own private sources we learn, that the course pursued by the disease is extremely similar to that which it followed in Russia, and that the same post-mortem appearances have presented themselves in the very few dissections which have been made. Brandy and opium have been extensively used as remedies ; indeed, a hogshead of the former, ready mixed in due proportion with laudanum, was supplied by government for the use of the poorer patients. A cholera hospital has been established ; but owing to the malicious report that the bodies of the dead were mangled, very few can be persuaded to avail themselves of it. One striking peculiarity, which is mentioned by several of the Indian writers, has been observed in the disease at Sunderland, namely, the ten-lency, in some cases, to sudden sinking after apparent recovery from the stage of collapse. Thus a man—we believe a sailor—was found with cold surface, blue skin, and imperceptible pulse ; brandy and laudanum were freely administered : in some hours after, he was found sitting up in bed, drinking gruel, and expressing great relief ; yet, from imprudent exertion, or other less obvious cause, the symptoms returned, were uncontrolled by the most powerful remedies, and he died next day. If there has been no cholera but what is

* Times, Nov. 18, 1831.

given as such in the returns, then the disease has not made much head, though the rate of mortality has been great; but if we are to regard all the cases of diarrhœa and common cholera as *the* disease, then has the rate of mortality been small. We see that they have at length ceased to return as diarrhœa those cases, some of which proved fatal in 24 hours; but their discontinuance shews that this part of the return was, to say the least of it, uncandid. As to their "common" cholera, it is evidently a very *uncommon* form of that complaint. Dr. Barry has been to Newcastle, where he found the report of the disease having broken out to be groundless: he has now returned to Sunderland.

—

WHAT IS MEANT BY LIVING WELL?

By far the most popular recommendation, as a safeguard against cholera, is "to live well," by which most people understand eating somewhat more than their accustomed quantity, and taking an extra glass or two of wine after dinner. No one certainly thinks of diminishing his allowance: even the habitual tippler protests that any withdrawal of his accustomed stimulus, however slight, leads to debility. It is high time that this pernicious misapprehension should be removed. "To live well," means to live "regularly," taking due nourishment, and no more—eating and drinking to support the body, not to pamper the appetite. Viewed in this light, we would ask how many there are who do not already eat and drink enough, and more than enough? certainly not one man of a hundred, in easy circumstances. Almost the only thing which prevents people from eating and drinking too much, is being unable to afford it. Our injunction to all those who talk to us about "living well," is never to take more than they can easily digest—to regard all fortifying against the cholera, which produces feelings of oppression, as so much assistance lent to the enemy—and more especially with regard to fermented liquors, that all exhilaration must be followed by its corresponding period of depression—and that he stands the best chance of exception who so regulates his diet and regimen as to be attended with the least variation of the pulse during the twenty-four hours.

These objections to an increase of the "creature comforts," apply with equal force to persons drugging themselves with bark or quina. Where there is much screwing up, the nerves will more readily become unstrung, and then is just the moment for any prevalent disease to make its attack. We cannot, however, but commend the exertions which are every where being made to add to the comforts of the poor: let the rich be assured that this is the most effectual way of keeping the evil from their own doors: the best way for them to live *well* is to put it in the power of their less fortunate brethren to live *better*.

—

VOLUNTARY DISPOSAL OF THE BODY.

DR. MACARTNEY'S document is now signed by upwards of 400 names, chiefly of professional men, who are anxious, by practical example, to remove the prejudices which stand in the way of dissection. We believe it is somewhat more than three years now since the document was prepared. Is it not time we heard of some *actual* example?—or who shall have the honour of the proto-martyrdom?

There is one obvious disadvantage attending this sort of post-obit bond in favour of anatomy: it leads the public to suppose that medical men are more interested in the matter than other people; whereas, there is no class of persons who would benefit so much by the entire prohibition of dissection as the present race of practitioners. Their profession would become a complete monopoly, and no fresh competitors could arise to "push them from their stools."

—

CONTAGIOUSNESS OF CHOLERA.

It is worth observing, that M. Brierre de Boismont, the companion of Le Gallois, and the first of the French physicians who published an account of cholera after returning from Warsaw, is a decided contagionist. Nothing can exceed the scrupulous accuracy with which he seems to have made up his mind on this subject. On one point he gives the most satisfactory assurances: the Polish army was free from epidemic of any sort previous to the battle (of Iganie) on the 10th of April: the cholera made its appearance immediately afterwards: and on three distinct occasions that a

healthy division of the army came in contact with the Russians, so often did the disease regularly develop itself.

Some papers on cholera, published under the sanction of the French embassy in Russia, and attributed to M. de Mortemart, furnish abundant testimony in favour of the doctrine of contagion: it is singular, however, that the non-contagionists have laid hold of these papers as favourable to their views, though M. de M. has distinctly stated in his 13th page, (what he frequently afterwards reiterated in substance) that "*le cholera est une maladie très sensiblement expansive dans les lieux où elle est arrivée, très subitement transmissible d'un lieu à une autre par l'intermédiaire d'objets matériels, soit vivans, soit inanimés.*"

M. LE GALLOIS.

THIS gentleman sunk, under the sequelæ of typhus fever, at Landsburg, in Prussia, on his return from Warsaw. He was only in his 26th year, but already distinguished as an able experimentalist in physiology. On the mission to Warsaw, he attracted general admiration by his energy, humanity, and talent. His opinions on cholera are incorporated with those recently published by his friend, M. de Boismont.

THE FINE ARTS.

M. DALMAS, from Warsaw, has presented the French Academy of Medicine with a series of drawings descriptive of the appearance of patients in the several stages of cholera. M. D. acted both the artist and the physician to his patients; and his work is said to have been executed with great skill.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Nov. 19.

MR. CHINNOCK IN THE CHAIR.

Discussion on the Question, is Cholera contagious?

THE meeting took place in the theatre, Great Windmill-street, and was very numerous attended; in fact, by far the most so that we have ever witnessed.

When the minutes had been read, Dr. GRANVILLE rose and proposed, that, after three nights' discussion, the question of contagion should be passed over; and he moved, that the society do now proceed to consider the nature and treatment of the disease. This motion was not seconded, and, in fact, could not be entertained, inasmuch as it had pre-

viously been decided and announced that the subject alluded to should come on this evening.

Dr. COPLAND thought that the number of direct and incontrovertible proofs of the infectious nature of the present disease, furnished by the speakers on his side of the question during the previous evenings, was so great as to render it unnecessary for him to go into this part of the evidence further than to advert to certain facts and considerations which had not been touched on by previous speakers. In respect to the direct proofs of the infectious nature of the pestilence observed in India, notwithstanding the representation to the contrary, they were so numerous and so strong, that two of the Medical Boards of the Presidencies had insisted on the existence of this property of the disease; and the third, after great hesitation, concluded by stating a decided opinion to the same effect. Even the non-infectionists furnished unequivocal proofs of the existence of the property against which they were contending. Of the various circumstances and phenomena of the disease there were none which in his (Dr. C.'s) mind more strongly evinced its infectious nature, and its origin from an infectious principle, than the specific and uniform character it has always presented, both in Asia and in Europe, and in every season, temperature, and locality. This specific and uniform appearance evinced a specific cause, reasoning from our knowledge of other specific diseases. Another circumstance, which he esteemed as distinctly proving its infectious nature, is the peculiar and particularly offensive odour which the disease is described, as observed, both in Asia and in Europe, to emit during life and after death,—a fact which is likewise observed in all other infectious maladies, and therefore shewing its close alliance in its infectious nature to them, particularly as the infection has been traced by the patients themselves to their having inhaled this morbid effluvia, in a very sensible manner, from the bodies of the affected.

Dr. Copland next adverted to the principal arguments which have been adduced by those who supported the opposite side of the question. They had assumed that, as the cholera of warm or temperate countries had, previously to the irruption of the present pestilence, been acknowledged not to have been infectious, this pestilence being cholera could not possess a different nature. But he insisted that the cholera of warm climates, which, in its severest forms, has been called *spasmodic cholera*, or *mort de chien*, was a totally different disease from the pestilence which has lately ravaged Asia and parts of Europe. The next argument on which the non-infectionists mainly depended, was the number of those exposed to infection who escaped it. But this was a circumstance common to this and all other infectious maladies, for all are not liable to be infected by

even the most virulent—all are not predisposed. As to the boasted non-infection from inoculation, &c. it proved nothing; for no concentrated virus being generated, it could not be thus propagated,—the materials for inoculation were wanting. Who would expect to communicate scarlet fever, or measles, by inoculation? The non-infectionists also laid great stress upon the number of those attacked, who could not trace the disease to an infectious source; but this, he conceived, is not otherwise than is to be expected, when we consider that a considerable period frequently elapses, in all infectious diseases, between the exposure to infection and the development of the disease. Even admitting only a few days to elapse, who could refer to a particular instance, or even to the several instances, of exposure to infection, either direct or indirect, which may have occurred during that time. The occurrence of epizootics was laid hold of by the non-infectionists, as a proof of the origin of the pestilence in a certain unknown state of the air, &c.; but it should be recollected that this disease had prevailed for fourteen years, and during so long a period was it not to be expected that the temporary coincidence of a more than usual mortality amongst some of the lower animals, with the prevalence of this malady, should be sometimes observed, particularly as epizootics are a frequent occurrence after very wet seasons? but the fact is, that the coincidence has been by no means frequent. As to the argument that the disease would have been kept out by quarantine if it had been infectious, the inference is devoid of weight, and entirely unfounded in fact; for, during the extension of the disease in the East, no quarantine was anywhere observed; and in the few places where it was more recently resorted to, under circumstances which could render it strict, it proved completely successful. When the infectionists argue, that this pestilence manifests a similar mode of communicating itself to that possessed by true typhus fever, one gentleman gets up and denies that this fever is infectious, and consequently that this pestilence must be non-infectious also. But as the false prophets, from whose mantle he has caught his inspiration, have not put their opinions upon record, they cannot be investigated. Every man of experience, and possessed of a sufficient range of observation, independently of the vast body of evidence upon record respecting it, proceeding from the highest and most experienced sources, knows how to deal with this objection. Without referring further to the many considerations which press a conviction of the infectious nature of the present pestilence, Dr. Copland concluded, that, although quarantine regulations could not be expected to succeed in thickly-inhabited and inland countries, they might have been successful as respects this country, on account of

its insulation, and that they had been therefore resorted to with the greatest propriety, and with reasonable expectations of excluding the pestilence.

DR. GEORGE GREGORY began by observing, that if the schoolmaster was abroad, so also was the teacher of physic, for in every society he found persons giving their opinions upon the contagiousness of cholera, and laying down the law upon one of the most difficult and abstruse doctrines in medicine—the origin and propagation of disease. Merchants, and lawyers, and men of fashion, undertake to decide, when they find that “the doctors disagree.” But do the doctors really differ? In this society, three gentlemen only have stood pre-eminently forward as anti-contagionists. One of them, Mr. Searle, avows himself, however, as still open to conviction. Dr. James Johnson acknowledges himself a *contingent* contagionist. With those gentlemen, he (Dr. Gregory) would not contend, but he was astonished beyond measure with the line of argument supported by Dr. Granville. He was at a loss to understand, why the able and conclusive arguments of Dr. Macleod and Mr. Burnett had failed to convince him, who, on former occasions, had proved himself so staunch a supporter of the orthodox doctrine. In this dilemma, he remembered that “his adversary had written a book,” and he sought, in its pages, a clue to explain the mystery. He believed he had found it. In that work (a letter on Plague and Contagion), Dr. Granville, after carefully dividing diseases into sporadic, simple epidemic, infectious or contaminating epidemic, and contagious, lays down two fundamental laws, or maxims:—1st, that epidemic diseases are never contagious; and 2dly, that contagious diseases are never epidemic. This, Dr. G. G. contended, was *prejudicing* the question. It precluded all argument, and all reference to fact. The cholera morbus was avowedly an epidemic, (that is to say, it attacked many individuals in the same place, at the same time, and in the same manner.) Now, epidemic diseases, according to the dictum of Dr. Granville, are never contagious. *Ergo*, cholera is not contagious. This was the logic of Dr. Granville. He (Dr. G. G.) protested against these *axioms*, and argued, that small-pox and plague are both epidemic and contagious. The error lay in drawing a broad line of distinction between contagion (whether mediate or immediate) and communication by a contaminated atmosphere, commonly called *infection*. Such a distinction does not exist in nature. Contagion and infection run into each other by insensible degrees. Some diseases, such as cow-pox and hydrophobia, require, for their propagation, that the miasm, or morbid matter, be applied to the *wounded* surface. Others, again, such as syphilis and tinea capitis, operate on the unbroken skin. The

effluvia arising from the lungs and skin in plague, extend a few inches from the patient's body. In the case of small-pox, the contagion extends through a chamber or ward, and even through the whole house; nor does there appear any reason for confining, even within such limits, the *sphere of contagious influence*. In some cases, it may possibly extend even across a street. What he and those with whom he was this night associated contended for was, *first*, that the cholera morbus was one of those diseases recognized by Dr. Granville as infectious or contaminating epidemics, (such, for example, as typhus fever and scarlatina); and, *secondly*, that infection or contamination of the atmosphere, by the *breath* and diseased secretions, is only a *modification of contact*. This expression, which, in point of fact, strikes at the very root of both Dr. Granville's memorable axioms, is actually to be found in that gentleman's work, (page 26.) Dr. Gregory proceeded to remark, that an absurd prejudice exists in the mind of many against acknowledging contagion (or communication from man to man) as a means of diffusing disease. It has been held up as unscientific, and as *cutting the knot* which the pathologist cannot untie. It has been called the last resource of the *ætiologist*, and only to be admitted when all other means of explaining the propagation of disease failed. He (Dr. G.) could never see the meaning of this, nor understand why a physician should entertain any scruples in acknowledging the influence of contagions, or *contaminating* exhalations from the lungs, skin, and vitiated secretions of persons labouring under disease. But, that such scruples were felt, and that very strongly too, was obvious, from the line of argument pursued by several gentlemen in the course of the debate. Mr. Searle, for instance, attributed the origin of the disease among the Polish troops to a long harassing march, and to the swampy nature of the ground on which they afterwards passed the night. When pressed, however, to say, whether the Russian prisoners, who had *not* made that same march, were yet similarly affected, his reply was, *non mi ricordo*. This silence, upon a point which would go far to settle the question at issue, was very significant. Dr. J. Johnson seemed inclined to refer the cholera to some unusual heat of the earth's surface, adducing, in support of this, the new Volcanic Island in the Mediterranean. Another gentleman strove to connect the appearance of cholera with some alleged irregularities of atmospheric phenomena; but what evidence we had of such, except the hurricane in the West Indies, he (Dr. G. G.) was unable to say. Upon the whole, he viewed these vague attempts at explaining the origin and propagation of cholera as the shifts of ingenious men, whose intellectual pride refused to acknowledge the simpler theory of *communication by contagious effluvia*.

[Either Dr. Copland or Dr. Gregory al-

luded to the fact that Mr. Orton had become a contagionist; to which Dr. Johnson objected, that little importance could be attached to the circumstance, as he was confined by illness in the north of England.]

DR. GILCHRIST having claimed the privilege of a visitor to address the society, proceeded to observe, that the evidence upon which the history of cholera is founded is unworthy of confidence. It was clear, he said, how difficult it was to come at facts, when we observed what was passing before us at Sunderland; how, then, were we to believe statements relative to Astracan? In reply to Dr. Gregory's remarks on Dr. Granville's opinions, as quoted from that gentleman's book, he (Dr. G.) begged leave to observe that Dr. Gregory also had written a book, in which the account of yellow fever was founded upon evidence the most fallacious that had ever been adduced. (The bitterness with which this gentleman spoke in some parts of his address, bore, we regret to say, but too strongly the appearance of his being actuated by personal feeling.) The Chairman begged Dr. Gilchrist to confine himself, as much as possible, to the question before the society.

MR. SEARLE offered some remarks in explanation of what had been said relative to him by Dr. Gregory; and in reply to the observations of Dr. Copland, that the pestilential cholera is a peculiar disease, different from all other diseases called by a similar name, he read a passage from (we believe) Jackson on Fever in the West Indies, in which a series of symptoms are described, the difference between which and those in some of the worst cases that he had witnessed in Poland, was to him inappreciable. This West India case, he had no doubt, was genuine cholera, though not appearing in an epidemic form.

DR. A. T. THOMSON rose to make some remarks on the character of the discussion, and spoke at considerable length on the importance of seeking truth rather than victory. The learned Professor then took an able view of the arguments on both sides of the question, and regretted that, in doing so, he was perhaps (really) obliged to repeat much that had been stated before by other members*. In conclusion, he declared himself perfectly open to conviction, and not wedded to the creed of either party, though the weight of the evidence greatly preponderated on the side of the contagionists.

DR. MACLEOD said, that when on a former evening he had addressed the meeting, unluckily for his argument, though not perhaps for the patience of his hearers the hour had expired while he was yet speaking, and he had thus been obliged to conclude abruptly, and without drawing the inferences which the facts he had mentioned appeared to him to warrant.

* It is on this account alone that we omit the details into which Dr. Thomson entered.

He would not, however, recapitulate what he had formerly said, but merely remind the society that he had dwelt upon three facts, as especially calculated to shew the manner in which the disease was propagated, viz. First, its mode of travelling from country to country, and from town to town, invariably appearing first on the frontier next to an infected district, or if on an island, always first shewing itself in a sea-port—in short, never being met with except where communication had been held with places in which it already prevailed. Secondly, the manner in which it frequently spread through the members of a family, or communicated itself to those who visited the sick, though residing in a different and distant locality. Thirdly, the immunity which had, in numerous well-authenticated instances, attended a rigid isolation, as at Peterhoff and Zarcozel0, where there were from 8 to 10,000 persons who remained unaffected, while it raged around them. But probably most men selected in their own minds particular facts from the general mass, and he would briefly mention one or two which, in his estimation, carried convincing evidence of the disease being propagated by human intercourse. In looking over the Indian reports he found that, as a rule almost universal, there was one spot in each great town which the pestilence long respected; while it decimated the adjacent district, one favoured habitation was either left untouched, or at all events was the last to suffer. This place was the jail. He doubted not (after the specimens of argument which he had heard on the other side,) that he should be told that the regular lives, and perhaps even the philosophic turn of mind, originating in their retired habits, gave to the dwellers in these secluded precincts their apparent immunity from the disease; but, unfortunately for this anticipated explanation, it happened that when once introduced it spread among the prisoners with great and relentless violence, shewing that there was no want of susceptibility, but merely a want of the necessary contamination. Another circumstance which had made a great impression on his mind, was the behaviour of the pestilence on entering Russia;—the manner in which it travelled *up* the Wolga to the north, and then, crossing over to the Don near its source, pursuing a course diametrically opposite, namely, *down* that river, to the south; thus travelling in two nearly parallel lines in contrary directions—a phenomenon perfectly intelligible if the plain straight-forward doctrine of it being carried by man were admitted, but wholly incomprehensible on any other. He had been accustomed constantly to hear, that they only thought the disease contagious who had not seen it, and this had long influenced his mind against the doctrine of contagion; but he had clearly proved, on the evening before last, that such was not the

fact—indeed, that in India and Europe, wherever Boards or Committees of medical men had been appointed to sift the evidence, they had always come to the conclusion that the disease was communicated from man to man; and here he particularly wished to correct an erroneous impression which had been made by what fell from Dr. Granville. That gentleman had stated, that when a committee of physicians was appointed by the Emperor of Russia, to decide on the contagious or non-contagious nature of the disease, they reported that goods did not convey the infection, *having previously stated that it was not communicated by man*. [Dr. Granville here exclaimed, that he had not said so, and that he would reply to this part of Dr. Macleod's observations; which intention, however, he did not carry into effect.] Such certainly was, if not the identical expression, at least precisely the meaning of Dr. Granville's statement, because he (Dr. Macleod) had at the time argued, that Dr. Granville was probably mistaken, else the fact of the report alluded to having led to the rigid exclusion of travellers by triple cordons on the roads, while merchandize was allowed to pass, became perfectly inexplicable. He alluded to the circumstance at present only to state, that he had since consulted the documents themselves, and found, as he had supposed, that although the Russian Board thought the evidence of cholera being conveyed by goods was not sufficiently strong to warrant the stopping of merchandize, they had no doubt whatever of its being conveyed by men. It appeared further, by the official papers lately published, that the Board consisted of forty physicians, of whom thirty eight held the disease to be contagious, and only two advocated the opposite doctrine. Against the numerous instances in which it evidently spread from one individual to another, the non-contagionists adduced examples of persons who had been exposed to the infection, if such it were, and escaped; but the multiplication to any extent, of instances where persons had *not* taken the disease, could never neutralize those where they had taken it. Calculations of the number who escaped might lead us to form some estimate of the proportion of mankind who are susceptible of the disease; but negative evidence can never, by any increase, disprove the positive results opposed to it. Yet this was the constant argument of the non-contagionists. Like the man tried at the Old Bailey for sheep-stealing—"Ah! my Lord," said he, "if I had known that you would have condemned me because two men swore they saw me steal the sheep, I would have brought twenty to swear they did not see me." Another advocate for non-contagion had just arrived on the field—Dr. Hammet, and the event was announced by a flourish of trumpets, the newspapers declaring that he had "several cases

which set the question at rest." Several cases to set such a question at rest! the very announcement shewed the utter ignorance of those by whom it was made of the simplest elements of medical reasoning. But let us inquire what the non-contagionists have to offer in lieu of that doctrine which renders the whole history of this malady, as to its mode of propagation, perfectly plain and simple. Why, nothing—absolutely nothing that will serve either to explain the phenomena, or even that is intelligible to others, whatever it may be to themselves. Thus we are told that cholera is produced by sol-lunar influence. In the name of common sense, what are the sun and moon about now more than they have been since the world began, that they should be accused of engendering this pestilential offspring? Others speak of subterraneous influence. Why do they not tell us what that influence is, which prevails alike in marshy jungles and on arid plains, on the summits of mountain ridges and in the depths of valleys—in every diversity of soil, climate, locality, and all that render things dissimilar. *Subterraneous* influence, not confined to the earth, but in some cases disregarding many hundred miles of intervening sea. This same subterraneous influence appeared to him to be but a subterfuge calculated to mystify rather than explain. It was in vain to grapple with things which had neither form nor body; they were too refined to comprehend, therefore too subtle and visionary for argument to impress. He could not conclude without remarking on the gradual conversion of the non-contagionists. [A loud expressive *hear!* from Mr. King.] As the gentleman had given to his exclamation such an expression of incredulity, he would adduce some instances. At these discussions those on the opposite side had begun by holding cholera not to be contagious at all; now they talked of it not being *more contagious* than typhus, or some other disease assumed to be contagious—this was notorious; and it was quite obvious that they who argued on the degree of contagion, of necessity assumed the existence of that property to some extent or other. Again, it was known to all that Dr. Russell went to Russia a non-contagionist, but that the film had fallen from his eyes, and he returned holding that doctrine no longer. Dr. Lawrie, an intelligent physician, who had seen the disease in India, and had been a non-contagionist, had just acknowledged, in the Glasgow Medical Journal, that farther evidence had changed his opinion; and though last, not least, was Mr. Orton, known as the author of a very valuable work on cholera, formerly a staunch non-contagionist, and who now said that the arguments against contagion were "as dust in the balance"—such were his very words—when weighed against those which are now opposed to them. Dr. James Johnson has made light of this, because he says Mr. Orton has not

of late seen the disease, having been confined to a sick bed. Granted; but these circumstances give additional weight to his opinions. He is now (said the speaker) removed from the scene of action, and can weigh the evidence without the prejudices of a partisan; that his recantation has taken place on a sick bed is the most convincing proof that it is—sincere. It was remarkable, that though the daily press was almost unanimously against contagion, the Reviews and Medical Journals were nearly all in its favour; and as they were better judges, this shewed where the evidence preponderated—indeed, one would think it scarcely possible that two opinions *could* exist with regard to a question where the Medical Gazette and the Lancet embraced the same side, and were seen fighting under the same banner.

Dr. STEWART begged that Dr. Copland would repeat, or more fully state, his opinion relative to the peculiar odour of cholera constituting a discriminative character of the disease.—[Dr. COPLAND explained: but we need not repeat what has been already incorporated in Dr. C.'s opening remarks.] Dr. Stewart, in resuming, observed that it appeared to him, after the very convincing arguments of the contagionists, that there could not be and there really was no difference of opinion in the society with respect to cholera; that all the members seemed to agree that the disease was contagious under certain circumstances.

Mr. BURNETT begged to be allowed a few words in explanation.

In maintaining the contagious character of cholera, he never intended to assume, indeed never did believe, that it or any other contagious disorder was always, and in every case, contracted by all who became exposed to its influence. On the contrary, he had discussed at some length the distinction between contagion and infection, and had insisted particularly on the very different degrees of communicability to be noticed in different disorders. Therefore the anti-contagionists, who, because they can cite the cases of some persons who have been exposed to the influence of cholera and have nevertheless escaped, think thus to confute the contagionists, only knock down a chimaera themselves have raised; for the contagionists have again and again referred to the truism, that many diseases which are sporadic in their origin may become epidemic and contagious—as, for example, typhus fever. Indeed (continued he) there is as much difference between a disease being *communicable* and *communicated*, as between an object being *visible* and being *seen*. An object may be, indeed many objects are, *visible*, which nevertheless are not necessarily *seen*; and a disease may be, indeed many diseases are, *communicable*, which nevertheless are not necessarily *communicated*. Moreover, the contagionists have the temerity to

attempt to prove a negative, and presume to declare that, because one, two, three, or more persons have been with patients suffering from cholera, and have escaped, therefore that cholera is not contagious. But can any conclusion be more illogical? If the cases of escape were ten times more numerous than they are—if, for every three, there were three thousand—they would avail nothing against even one well-marked and decided case of direct communication; all that they could legitimately be brought to prove would be the comparative facility of communication—the relative degree of contagiousness. Indeed, to this point do most even of the former non-contagionists seem to be veering; for one declares that it is *no more contagious than typhus*, and another that it is *contingently contagious*, Dr. Gilchrist being the only spokesman who now dares to uphold the unblenched banner of non-contagion. But what do these gentlemen mean by *contingent contagion*? Are not all contagious diseases *contingently contagious*?—and are not these *contingencies* the predisposing states of the patient's health? This, which they now so readily grant, is all that the contagionists ever have desired: yet why, when they are with us as to *facts*, are they not with us in *names* also?—for what will the public understand by their strenuously repeated affirmations that cholera is *not contagious*? Will the public understand that it is *contingently contagious*?—will they not rather suppose them to mean that it is *not communicable*?—and then, should such a dire disease be suffered unimpeded to devastate this great town, will not the anti-contagionists be rightly accused of breaking the word of promise to the sense, even if they seem to keep it to the sound.

As to the statement of the learned member, Dr. Thomson, that the speakers have appeared to him to be contending for victory rather than for truth, it may be a sufficient answer to acquaint him, that had he been present at the former meeting he would have known that the very course he himself just now pursued, to arrive at truth, was the course that the contagionists have several times journeyed over for that very purpose; that Dr. Macleod, Dr. Sigmond, Mr. North, and himself, have over and over again been obliged to prove and re-prove the facts of communication; that they had traced the progress of the disease from place to place—had shewn that as man travelled it travelled, that as man stopped it stopped; that when communication was interrupted its progress was interrupted; that as travellers journeyed round, it journeyed circuitously with them; and in continuation of these arguments, Dr. Macleod had this evening, among other points, well noticed the important fact that the last places infected with cholera had been the gaols. He might likewise have shewn, not only that it attacks last those places which are most

secluded, but also that it attacks first those which are the most public; for where does cholera first break out?—why, in sea-ports and frontier towns. Where has it first set its foot upon our own land?—why, it has been true to its general rule, and chosen a sea-port town for its invasion. Mr. B concluded by denying that the contagionists formed any party; he came open to conviction; he came, not only willing, but anxious to believe in the non-contagious nature of the disease; but he could not shut his eyes to facts, nor resist the force of evidence. He would not follow truth so far, and so far only as she concurred with prejudice, but was ready to give up all preconceived opinions, and follow the path her unerring finger should point out, well knowing, that although both Socrates and Plato are worthy friends, that the better friend is truth.

MR. KING appealed to the society if his was not the true view of the matter. All diseases were contagious. Was not lues venerea a contagious disease? Very well. And typhus? and phthisis? If nobody rose to dispute it with him, he would take silence for consent (loud laughter). He was ready to prove it, if he was to stand there on his legs till three in the morning (cries of question). With regard to cholera, he had only to say that he was proud of agreeing with Dr. James Johnson: and denied that that gentleman and he had changed their opinions as somebody had stated (laughter.)

A member proposed that a resolution to that effect should be adopted by the society; but this was very properly overruled.

After much desultory conversation, which protracted the time considerably beyond the usual hour for breaking up, it was moved by Dr. J. Jonsson, and carried unanimously, that on next Saturday (this) evening, the Nature and Treatment of Cholera should be discussed.

NOTICES.

Mr. Addison's paper has been received, but is unavoidably postponed, owing to the great press of matter on the engrossing subject of cholera.

The communication of Dr. Baron came to hand in time, but it was impossible to comply with his request by inserting it this week.

The papers of Dr. Marshall Hall, Mr. Key, Dr. Campbell, (Edinburgh), Mr. Battley, Dr. Wilkinson, a Constant Reader, Philalethes, a Chemist and Druggist, Y. Z. Mr. Copland Hutchison, a Correspondent (whose name we cannot make out), dated *Helston*, Mr. Bennett, Mr. Spence, *Non-Nemo*, Mr. Ward, Mr. Knott, Dr. Badlam, Mr. Bushell, Mr. Crowdy, Mr. Slater, Mr. Green, Physician, Dr. Stanley, Mr. Lawrance, have been received.

A Pupil (Borough) next week.

Philomelides: we are sorry that at present we cannot.

LECTURES

ON

THE THEORY AND PRACTICE OF
MEDICINE ;

Delivered at the London University,

By DR. ELLIOTSON.

PART I.—LECTURE IX.

Inflammation (continued).—Appearances of the Blood: Buffy Coat—Coagulation.—Terminations of Inflammation: Resolution—Effusion—Suppuration.

AFTER speaking, gentlemen, in the last lecture, on the general subject of inflammation, as shewn in the solids, I began to mention that certain changes are observed likewise in the blood. I merely entered upon the consideration of these changes.

I stated, that very frequently, when a part of the body is inflamed, the blood which is drawn from a vein does not exhibit the appearance which we observe in health, but that the red particles separate from the fibrin, so that the latter remains colourless on the top, forming what is called "the inflammatory buff, or buffy coat." I stated that this was sometimes drawn into an excavated form, and then it is said to be "cupped;" so that the blood may be buffed and cupped.

I mentioned, however, that though this is frequently observed, yet you may have the most violent inflammation without any such appearance as this in the blood. If you find such an appearance, and you suspect inflammation, you will certainly have so much the more reason to believe in its existence; but if you have tolerably sufficient evidence that inflammation is present, you are not to doubt its existence because when you draw blood you find it is not buffy.

Buffy Coat.

I now proceed to the farther consideration of this subject. The buffiness of the blood is not proportionate to the danger of the disease. I mentioned, that, in the case of mere pregnancy, you sometimes have buffi-

ness; but where inflammation is present and the buffiness likewise, the latter is not necessarily in proportion to the danger; for, in acute rheumatism confined to the joints, you will often find the blood in a high degree buffy and cupped, although there is not the slightest danger in the complaint.

Many particular circumstances are necessary to be observed in regard to this phenomenon. The first cup will often be buffy, when the second, taken within a minute or two, is much less so, or perhaps not at all. When this circumstance occurs, I believe the difference generally arises from the amendment of the patient; for the beneficial effect of bleeding is sometimes very striking—it sometimes immediately checks the inflammation, and one may conceive that a certain portion of benefit in such cases takes place before half the blood we intend to withdraw is removed; and when the second cup exhibits less buffiness than the first, we may ascribe it to the actual amendment of the patient. The fibrin which forms the buffy coat is found to be more abundant in inflamed than in healthy blood; and it is actually found—at least we are told so, I have no observations of my own upon the point—that the quantity of the fibrin varies in different cups taken from the patient at the same bleeding; that the blood of the first cup shall contain actually more fibrin than the blood of the second; that the bleeding actually induces a change in the blood itself; that not merely the buffiness, but the quantity of fibrin, whether it form buff or not, is found to vary in different cups; and that generally it is most abundant in the first cup.

Coagulation.

Before, however, I proceed to the consideration of the cause of this phenomenon—buffiness—I must say a few words upon the coagulation of the blood in general. It has been contended by some, that the formation of the coagulum is to be attributed to the death of the blood; but this I cannot assent to, and

for this reason—because a coagulum will often become organized; vessels will actually form in it, not merely shoot into it, but vessels will form in it, and unite with the surrounding healthy parts. I therefore cannot ascribe coagulation to the death of the blood. Sir Everard Home declares that he has seen vascularity in a coagulum when detached, when there were no vessels at all to shoot into it, but when, by its inherent vital power, it had produced vessels. I therefore cannot believe that the coagulation of blood is the effect of its death. John Hunter, on the other hand, ascribed the coagulation of blood to its life; I cannot, however, assent to that opinion either. Freezing is known to kill eggs; and that process must be supposed, therefore, to kill blood; but if you freeze blood and then thaw it, the moment it becomes liquid it coagulates, just as though it had never been frozen. You must suppose this blood to be actually dead, and its subsequent coagulation, therefore, cannot be ascribed to its life. Sir Charles Scudamore says, that when blood coagulates, a certain quantity of carbonic acid escapes; that the blood coagulates sooner accordingly as the circumstances in which it is placed favour the escape of carbonic acid; and he consequently ascribes the coagulation of blood to the escape of carbonic acid. Now it is a fact, that the more blood is exposed—if it be allowed to trickle down the arm instead of coming immediately into the receiver—the more it is exposed in that way, or by being received into a large shallow basin, which presents a greater surface to the atmosphere, instead of into a small vessel; or if it be received into a vessel calculated to retain the heat, and consequently not allowing the blood to cool so rapidly, and more especially if it be received into a vessel actually warm; it is said that, under all these circumstances, the escape of carbonic acid being favoured, it coagulates the sooner. This may be all true; but we have very high authority, as high authority as we can wish for—namely, that of our own Professor, Dr. Turner—for stating that no carbonic acid escapes from the blood during coagulation. When we consider, that, in the same dead body, we have a quantity of blood liquid in one part and coagulated in another—and nothing is more common than to find this the case in the different cavities of the heart, and in its different large vessels—I cannot ascribe the coagulation of blood either to its life or death, or indeed to any escape of carbonic acid; I therefore beg to say that I do not know why blood coagulates. I am not satisfied with the reasons that have been given, but I am not prepared to advance another reason instead of them; and it is always a great point gained to know one's ignorance.

The buffness of the blood is certainly affected by the slowness of the coagulation; so that if the blood do not flow freely at first,

but does afterwards, the quick coagulation of the first cup may not give the red particles time to subside, and this may prevent its being buffy. Hence you see that the quick or slow coagulation of blood must affect its buffness. As blood coagulates the sooner the more it is exposed, and therefore the more slowly it trickles down the arm, a thus increased quickness of coagulation may prevent blood from being buffy which otherwise would be so; and when it comes out more freely into the second cup, it may coagulate more slowly, and then, if there be a disposition to buff, the buff will form; so that it is not at all uncommon to have no buffness in the first cup, but to find it in the second. Therefore, although a patient may have improved from bleeding, and have a disposition to form less buff in the second cup than in the first, yet the accidental circumstance of its trickling down the arm into the first cup may give rise to an opposite occurrence, and may counterbalance the operation of the benefit. You may have buffness in the first cup and none in the second, from the improvement of the patient; or you may have no buffness in the first and find it in the second, notwithstanding the patient has improved, from the accidental circumstance of the second cup coagulating less speedily than the first.

But although the quickness and slowness of coagulation can affect the formation of buff, yet they are not the cause of it; for it has been known that, of two portions of the same blood, one has continued fluid ten minutes after the other had begun to form buff, and yet has shewn no buff. When the stream of blood is exactly the same, causing the blood to flow into cups with equal rapidity, you will sometimes find the difference of buff to be exceedingly great; and you will sometimes find the buffness to be the same when one cup has coagulated very slowly, and the other very quickly. Dr. Stokes has given us some experiments upon this point, in his *Pathological Observations*. He has furnished twenty-seven experiments, in fifteen of which buff was formed, and in the other twelve it was not. Among the twelve in which no buff was formed, no coagulation took place in three of them in less than from twenty to forty minutes; and in four there was no coagulation for eight minutes. There was abundance of time, through the slowness of coagulation, for the red particles to separate from the fibrin, and yet the result was as I have stated; whereas, in the fifteen in which buff was produced, not one specimen delayed to coagulate longer than fourteen minutes, and in all but three coagulations took place in five minutes; and yet buff was produced. The real cause of the buffness of inflammatory blood, therefore, certainly is not the slowness of the coagulation; but from what it proceeds, I do not know. It may be owing to the thinness of the fibrin; for it ap-

pears to be a fact, that the fibrin of buffy blood is both thinner and more abundant than that of other blood. If it be thinner, one may conceive that the red particles will more easily separate from it, and subside to the bottom. That may be the reason, but I do not say it is. As the quantity of fibrin is known to vary during the flow of blood, so probably may the thinness; and this may be the reason why blood which shewed buffiness in the first cup exhibits none in the second—the blood being thicker, the red particles do not so easily separate. However, the buffiness of the blood is not proportionate to the slowness of the coagulation. Dr. Stokes' experiments confirmed the opinion I had formed before from observation and reading, yet I believe it is true, that generally buffy blood coagulates more slowly than other blood, although I do not ascribe the buffiness to this circumstance; and the slowness of coagulation may be in a great measure owing to the thinness of the fibrin; if the fibrin be thin, it must probably be less easily disposed to solidify. It is said that the mere celerity of the circulation does not effect any changes in the quality of the blood; that it is not because the pulse is quick in inflammation that the quality of the blood changes; for Sir Charles Scudamore says, for example, that where there has been great celerity from pure fever or exercise, and blood taken away, no buff has been observed. This, however, has been denied by others.

Although, however, inflammatory blood shewing buff generally coagulates more slowly than other blood, yet the buff coagulates, if there be strength of body, very firmly—more firmly than the crassamentum in health. However, the firmness and the cup-like form are usually proportionate to the strength of the patient; but it is to be remembered, that the firmness of the coagulum is sometimes very great, without there being any cupped appearance. Certainly the firmness of the buffy coat is usually proportionate to the strength of the patient, and the firmness and cupped form are said to be greater, though I do not know that they are, in inflammation of fibrous membranes, such as aponeuroses, ligaments, and tendons, and in the inflammation of serous membranes, than of other parts.

If it so happen that the buff of the blood be not firm, then the blood is said to be *siety*; and when the coagulum of blood is soft, whether it be buffy or not, generally I believe you will find the serum too abundant;—at least when the blood is watery you will usually find the coagulum soft, whether it be a red coagulum or a buffy one. Two writers, Trail and Gendrin, one in our own country, and one abroad, say that the serum of inflammatory blood is altered in quality—that it contains twice as much albumen as is found in health.

The cupped appearance of the blood, in-

dependently of the buffiness, is very much affected by the size of the vessel into which you draw it. If you extract the blood of a patient into a tea-cup, you have an infinitely greater chance of finding it buffy than if you draw it into a hand-basin; the larger the vessel, the less is the disposition to form the buff, and likewise to form the cup appearance. For accurate observation blood should be drawn certainly into small vessels.

These are the gross changes, if I may so speak, in the blood; but some writers say that there are still more minute changes. Dr. Hastings says that, with a microscope, he found the blood in inflamed capillaries of a deeper colour than usual, as it were broken down, homogeneous, with no appearance of red particles. The remark does not apply to the general blood in the system, but to that of the inflamed vessels themselves. He says that in three experiments there were flocculi in the inflamed vessels, which disappeared as he directed his eye toward the healthy vessels. What these flocculi were, I do not know; whether they were exceedingly minute coagulations of lymph, formed from the slow motion of the blood—for it moves more slowly in an inflamed part—and which were re-dissolved when they reached the vessels where there was a proper motion, I cannot tell.

It is a general observation, that the blood is very black in the neighbourhood of inflamed parts; and when you apply leeches it is not till the latter end of their application, and perhaps not till after several applications, that it becomes bright. This is a fact: you will find that the blood which comes away first is generally very black, whereas the blood that streams afterwards will become brighter; but it will sometimes remain black till the second or third application of leeches. I have observed this frequently, and I presume it arises from this circumstance, that the blood, from moving slowly, acquires more of a venous character. I have known the blood, times innumerable, black on the first application of leeches, and I once knew the blood, in the case of chronic inflammation of the liver, highly offensive, so that almost as soon as it was removed it went into a state of putrefaction; but as leeches were applied day after day, it became brighter and brighter, and at last regained its natural odour and nature.

It would be wrong to consider inflammation as merely affecting the solids; it affects likewise the blood itself.

Terminations.

Now inflammation may terminate in complete health of the part—the part may in a direct manner regain its former state; and when this is the case, it is said to terminate in *resolution*. But generally when there is this resolution, there is some increased secretion, either at a distant part, or if the or of affected be of a secreting character part it

itself. If it be a serous membrane, there is more or less effusion; if it be a cellular membrane, there is a more or less oedematous condition, which you can observe externally. But if these things be very slight, only temporary, perhaps no inconvenience is produced, and the termination of inflammation is then said to be in "resolution." If, however, it be a serous membrane that is attacked, and there be a copious secretion, it is said to terminate in *effusion*. If it be a cellular membrane that has been inflamed, and it does not terminate in resolution, a new fluid is continually formed, called *pus*, and the formation of this new fluid is denominated *suppuration*. If it be a mucous membrane which has been affected, you generally have a great discharge either of mucus or pus, so that you may have suppuration either from a cellular or a mucous membrane. It is actually pus that is formed continually in inflammation of a mucous membrane; nay, you likewise have pus produced from the interior of a vessel. But it is right to say, that although authors call these "terminations," yet these copious secretions are not necessarily terminations, and that when they begin, it is not a matter of course that inflammation shall end; we ought rather to say, I think, that inflammation sooner or later induces effusion—induces suppuration, because the inflammation does not always cease when they take place. Although the part may suppurate, or fall into a state of effusion, still these processes may be inflammatory—you may still have to go on with anti-inflammatory measures—you may still have heat, pain, tenderness, and all the marks of inflammation. We ought, as I have just observed, rather to say that inflammation, sooner or later, induces these changes, or that these occurrences take place in inflamed parts, the inflammation subsiding or not, just as the case may be. Inflammation may terminate, however, not in health, directly or after these processes, but in *death*, either general or local. You may have inflammation destroy life without any farther change taking place than the occurrence of inflammation itself. It is very common to see persons die of enteritis, without mortification or any other change than inflammation. It sometimes happens, however, that inflammation does not destroy general life, but the life of the individual part, and then it is said to terminate in *mortification*. But the inflammation may still continue, not in the dead part, but in those around, and extend farther till more parts die, or not, just as the case may be.

Resolution.

I will now speak particularly of these various "terminations," as they are called; the first of which—resolution—is really a termination. Now when an inflammation is resolved, all the symptoms decline, and no fresh symptoms arise; and this is essential

to the character of resolution. In this state the urine generally deposits an abundant red sediment. When the inflammation is going on, the urine is generally high-coloured, but clear; but when the inflammation subsides, there is usually a copious red sediment, and the reason of this, as given by chemists, is the following. In healthy urine there is lithate of ammonia, which is pale and white, as also a yellow colouring matter, the nature of which is not known, but which is thought to be perhaps a modification of lithic acid. If to lithate of ammonia out of the body you add what are called the *purpurates*, you immediately produce a pink substance, such as you find in hectic fever; and if the urine have its usual yellow colouring matter, a mixture of that with the pink appearance produced by the purpurates and the lithate of ammonia, gives a red colour—pink and yellow mixed together form a red colour. Now in this diseased state of things, nitric acid, as chemists tell us, is formed in excess in the urine, which acts upon the lithic acid, and converts some of it into a new acid, called *purpuric*. This purpuric acid, uniting with the salts of the urine, makes the purpurates; and these purpurates, mixing with the lithate of ammonia, which is always in the urine, produce a pink deposit, which pink deposit, united with the yellow colouring matter, becomes red. The lithate of ammonia and soda are formed in some degree of excess in the urine under inflammation, and nitric acid is produced, which, as I have said, acting upon the lithic acid, produces purpuric acid, so that the purpurates are formed. These, mixing with lithate of ammonia, produce a pink substance; and when this unites with the yellow colouring matter, the colour is changed to red. This is the reason why the deposit is red. The reason why the urine is red without sediment till the inflammation declines is this—the same substances are in the urine, but held in solution during the activity of the complaint; but when it declines, an excess of lithic acid is formed, producing super-lithates, and these are very insoluble, and therefore a great portion of them falls down in the form of a precipitate; hence you have the red sediment. This is the explanation given by one who understands these things better than any other man perhaps in Europe—I mean Dr. Prout. You find these changes in the urine: the deep-red colour, with transparency, during the activity, and the copious red deposit during the termination of the disease; and you find these very same things from the most common cold, and certainly often in the same abundance.

Effusion.

If, however, the inflammation do not terminate in resolution, but produce such an effusion as from its quantity can do harm, then, when the symptoms of the inflammation

subside, or indeed whether they subside or not, you have a fresh set of symptoms come on, from the compression of the parts. For example, if the pleura have been inflamed, and the inflammation induces at last copious effusion, after the pleuritis has subsided, you have a fresh state of symptoms, dependent upon the compression of the lung. When there is this excessive effusion, however, in a serous membrane, there is generally something more—fibrin is usually thrown out, sometimes forming layers, sometimes diffused in the serum, and forming flocculi, larger or smaller, so that the serum is turbid, and not only turbid, but you may have flakes in it. When serum is thus poured out in a serous membrane, it is at last often entirely absorbed while the fibrin remains; and frequently we find fibrin where there is no appearance of serum, the serum having been absorbed, or fibrin alone having been produced. Fibrin, so poured out, has been seen in so short a time as four hours after the commencement of inflammation. Professor Thompson, of Edinburgh, says that he has seen lymph lying on a serous membrane within four hours after he had induced the inflammation. Sir Everard Home says, that he has known an effusion of fibrin form vascular adhesions in the course of twenty-four hours. So rapid are these changes, that it appears inflammation may cause an effusion of lymph in four hours; and that within twenty-four hours from the very first, this portion of fibrin may become an adhesion, containing blood-vessels. Sometimes the effusion which occurs is not serum, is not lymph, or serum and lymph, but is pus; so that you may have the pleura, the pericardium, or the tunica vaginalis, filled with pus, and sometimes you may have a mixture of pus and serum.

Suppuration.

If the third effect of inflammation take place—not resolution, not effusion, but suppuration, then the pain indeed generally ceases, but the swelling which was present during the inflammation still remains; and if there were not much swelling before, perhaps there is a good deal now. This swelling, however, does not, as when a part is inflamed, feel hard, but is for the most part soft, and frequently you may discover fluctuation early. Sometimes you cannot discover this at first, but as the fluid increases, you discover more and more, till the fluctuation is most decided. The pain, however, does not always go away; it may decline at first, but as the fluid increases, you may have fresh pain from tension of the part; the part may become exceedingly tense from the quantity of fluid, which afterwards is absorbed, or escapes either by art or nature. There may be very considerable pain. Besides this, just as in effusion of a serous membrane, where there is suppuration of a cellu-

lar membrane, or of any organ, you may have fresh symptoms from pressure. That, however, depends upon the situation of the part; if the part in which the pus collects be one which will suffer from compression, then you may, of course, have fresh symptoms from the mere compression. But besides this, if the suppuration be extensive, you have general shivering. As soon as the matter forms, or when it is forming, or soon after it, what are called *rigors* take place; and after a time you have great heat and sweating—in fact, you have what is called *hectic fever*.

Hectic Fever.—Now this hectic fever is marked by a quick, but weak pulse, by heat of the whole surface, but particularly heat with a red flush upon the cheeks, the palms of the hands, and the soles of the feet. Sometimes the whole of these are red, but more frequently the redness is partial, forms patches, so that a portion of the cheek, the size of half-a-crown, more or less, may be intensely red, while all around is of the usual pale character. In addition to these symptoms, the patient has profuse sweating, so that as soon as he falls asleep he is almost sure to fall into a sweat, and frequently when not asleep he still sweats. These symptoms are aggravated generally at night, and frequently also at noon, and indeed at any time when food is taken. It is remarkable to notice the effect of sleep upon the sweats. If a patient fall asleep but for two minutes, although he may not know it, it is very common to find these sweats break out, and they are frequently very partial, being observed particularly about the head and chest.

In this state of things, the sediment of the urine is not red, but pink. I should have said, that when it is red it is called *latteritious*, looking like a brick. In hectic fever, when the suppuration is going on, the sediment is of a pink colour. The chemical changes are precisely the same, the purpurates acting upon the lithates, and producing this pink colour; but this pink colour is not changed to red, because it appears that the yellow colouring matter of the urine is absent, and therefore the pink of the purpurates and lithates remains unchanged.

Frequently in this state of things, the intestines pour forth a fluid as abundantly as the skin, so that you have purging, and not unfrequently the purging alternates with the sweating, so that if you have an increase of the sweating, there is a decrease of the purging, and *vice versâ*. This sweating and this purging are called *colligative*; melting the patient down, and hence the name. The alimentary canal often becomes inflamed, and when you open a patient who has laboured under this state, you find the mucous membrane red, sometimes ulcerated, and the tongue is at length red: you may see it yellowish, or of a deep brown colour, but for the most part it

is red, either at the surface, or at the tip, or at the sides and tip. The mind generally becomes very quick, the patient is excessively alive to every thing, and, at the very last, a degree of delirium takes place; and, when that occurs, it is usually the precursor of a fatal end. I need not say there is usually extreme debility and wasting of the body.

It is to be remembered, however, that these symptoms, called hectic fever, may occur without any suppuration. They will occur, I know, from mere depression of mind; they will occur frequently in women from excessive suckling—from suckling too much, or suckling too long. All these symptoms, without suppuration, will sometimes remain for a great length of time, and the patient at last, by proper management, do very well.

Abscess.—If the pus, which is formed, be collected into a mass, we term the collection an *abscess*. Supposing the formation take place in a cellular membrane, fibrin is thrown out, and the cellular membrane, exterior to the fibrin, becomes more dense and more vascular. A cavity is formed in the lymph, containing the pus, and the exterior of the cavity is formed of the condensed cellular membrane. This lymph, forming the cavity, is gradually absorbed in one part, and that part is usually one which is nearest to the surface, or some exit of the body; so that if it be nearest the surface of the body, the portion nearest the surface is absorbed; or if it be near the intestines, the portion nearest the intestines is absorbed, and so on. Wherever there is the easiest exit for the contents, there the fibrin becomes absorbed. This is a very extraordinary and beautiful provision of nature. If there be a possibility of the pus escaping into a part where it might do harm, adhesions are formed all round that situation, so as to prevent the escape of the pus into it. Nothing can be more wonderful in pathology than this—than the process of nature in giving exit to the matter in a way the most calculated to facilitate, and in taking steps the best calculated to prevent mischief.

CLINICAL LECTURES,

Delivered in the Dispensary of the London University,

By DR. ANTHONY TODD THOMSON.

LECTURE VI.—Nov. 17, 1831.

Chorea—Melancholia.

GENTLEMEN,—The case of Chorea, which I noticed in my last lecture, is still upon our books. The violence of the symptoms abated after the bowels were effectually cleared, and the Carbonate of Iron had been taken for a few days; but, owing to the neglect of the mother of the patient, the bowels became confined, and two days ago the irregular movements increased to a greater

degree than when the girl was first brought to the dispensary. The use of the purgatives has been again resorted to; and, with the view of obtaining the effect of the Carbonate of Iron in its most efficient form, it was ordered to be prepared by adding sixty minims of the tincture of Muriate of Iron to a mixture consisting of one table spoonful of a solution of two ounces of Bicarbonate of Soda in a pint of water, a dessert spoonful of a saturated solution of sea Salt, and a third of a pint of water. By swallowing this dose at the moment of mixing it, two grains and a half of pure Carbonate of Iron are taken, in a state the best adapted for securing its influence upon the nerves of the stomach, and consequently for obtaining its tonic effect; and, if the statements of Mr. Phillips respecting the quantity of Protocarbonate of Iron in the Subcarbonate, usually met with, be correct, this dose is equivalent to sixty-five grains of that preparation. The chief object of the Muriate of Soda is to keep the bowels open under the influence of the Carbonate of Iron, without the daily use of more active cathartics. I will now, gentlemen, take advantage of the opportunity, which this case affords me, of making a few remarks on Chorea.

The condition of this patient, Margaret Brady, has enabled you to form an accurate idea of the most prominent symptoms of this curious disease; the jerking movements of the legs and arms, the constant restlessness, the twitchings of the face, the agitated, irregular movement, on raising the leg in the effort to walk, the difficulty of putting the foot firmly to the ground, the partial defect in articulation, and the almost entire want of controul over the voluntary muscles. These movements vary in almost every case of the disease; and, in some instances, exhibit the most singular anomalies. Thus, in one case related by Dr. Clarke, of Nottingham, and published in the fifth volume of the Edinburgh Medical and Surgical Journal, we find symptoms in several respects resembling those of Hydrophobia; for instance, the ordinary irregular movements were accompanied with a constant snapping motion of the lower jaw, which was sometimes so violent as to require the jaw to be held; there was great susceptibility of cold air on the surface, and a dread of swallowing liquids, owing to spasms being excited the moment they touched the fauces, with a catching of the breath and convulsive respiration. In another case, detailed by Mr. Kinder Wood, in the Medico-Chirurgical Transactions, the disease strongly resembled Tarentismus; the individual had an immoderate propensity to dance, and the movements kept time to a tune which dwelt in the mind of the patient. But such anomalies are rare, and in common the external symptoms of the disease are such as you have seen them in the case under treatment.

With these more obvious symptoms there is often a very variable, sometimes ravenous appetite, a fulness and hard state of the abdomen, and a constipated state of the bowels. The vivacity and playfulness natural to the age in which the disease most frequently occurs, is lost; and, if the attack be obstinate and long-continued, the eye loses its intelligence, and the countenance becomes pale, languid, and expressive of vacancy, or the approach of fatuity. In a few cases the involuntary movements have continued during sleep; in others, as in the case before us, they cease only at that time. You will find that some writers, for instance Darwin, assert, that the will can so far controul the movements, that the patient can lie still in bed if he please; but experience is directly at variance with this assertion; and in Brady's case, although the movements cease during sleep, yet, she cannot controul them in bed when she is awake.

The greater number of the cases of Chorea terminate favourably; nevertheless, in a few instances death has occurred, but only in those of greatly weakened constitutions, in which the continuance of the convulsions and the want of rest have actually worn out the strength. But if death seldom occur in cases of what may be termed *idiopathic Chorea*, it is almost always the result of that form of the disease which sometimes accompanies rheumatic fever; in which case, post mortem dissections have displayed inflammation of the spinal meninges, softening of the cord itself, or, as I have seen in two cases, following rheumatic metastasis, inflammation of the sheaths of the phrenic nerves, and those of the nerves of the cardiac plexus. The last-mentioned variety of Chorea has not, as far as memory serves me, been noted by any writer on the disease.

It is almost unnecessary, gentlemen, to inform you that Chorea is a disease connected with, or dependant on, a highly irritable condition of the nervous system. This nervous constitution, or temperament, displays itself by an unusual degree of sensibility and susceptibility of impression; so that circumstances which, in a healthy constitution, are indifferent, produce in this inordinate actions, with or without pain. As this state is apparently sometimes congenital, it may be reasonably inquired whether it is likely to depend upon any variety of organization in the brain and nerves, which would tend to regulate and modify ordinary impressions? or whether it is merely the result of a greater quantity of blood sent to the brain, and disposing it to be more excitable than when such an excess does not exist? In reply to these queries it may be stated, that we have no evidences of peculiar organization, or structure, in the brains of individuals of a highly nervous temperament who have suddenly died, and whose bodies have been examined; and that, although an increased impetus of blood to the head, short of the

extent which would produce actual disease, may augment this nervous temperament, yet we have no demonstrative evidence of the existence of such an impetus. The pulse is not stronger, the head is not hotter, nor is there any greater redness of countenance than in the more usual condition of the habit. But whatever may be the state of the brain in this diathesis, or nervous predisposition, it is undoubtedly such as to occasion a tendency to spasms and convulsions, from a degree of impetus less excessive than that which the ordinary state of the brain would require for their production. This, therefore, may be regarded as the predisposing cause of Chorea; and, under its influence, whatever circumstances augment the action of the heart and arteries, whether these be mental or corporeal, such an impression is made as to induce those irregular catching movements which constitute the most striking feature of this disease, and which occur chiefly while the muscles are thrown into action during the process of volition. It is certain that chorea is aggravated by whatever increases sanguineous action, and that it has occasionally followed blows, and other injuries of the head likely to induce a state of chronic inflammation in the brain; but it is also as certain that it has arisen from a very opposite condition of the system. In saying this, however, I must guard you against the opinion that it is always a disease of debility; there can be no greater mistake. Nor is it less erroneous to suppose that spasm is, in every instance, a symptom of a weakened state of habit. One of the most common exciting causes, acting upon the diathesis to which I have referred the disease, is local irritation in the bowels, which is afterwards sympathetically communicated to the whole system. This irritation may be set up by improper diet, by dentition, or by worms; and whichever of these is present, the effect is forcible in proportion to the greater original delicacy of frame of the patient; and it is always fostered by confinement and by sedentary occupations.

In referring to dentition as an exciting cause of Chorea, you must not direct your attention solely to the protrusion of the first set of teeth, as an equal degree of irritation may occur during the progress of the second. In general, the convulsions attending the first dentition resemble those of Epilepsy; whilst the consequence of the irritation of the second, is more frequently Chorea. Why is this? you may naturally inquire; but the question is more easily put than answered. With regard to worms, were these a common cause of irritation producing Chorea, we should find the disease more common than it is in adults; for although the period between childhood and puberty be that in which intestinal worms are generally found, yet these parasites are present in almost every period of life, whilst Chorea

most commonly makes its attack between the eighth and the fourteenth year. No exciting cause is more frequent than crude and indigestible diet; and, in the case now under consideration, it can be assigned to no other.

The irritation connected with the uterine function, when the change which takes place at puberty is retarded, is another exciting cause of Chorea in certain habits; and is another proof how much congestion is connected with its attack. In some instances, also, the disease has evidently originated from repelled eruptions. Mental emotions, likewise, act as exciting causes of Chorea; but in these cases we may generally trace a previous low state of habit, with much sallowness of complexion, and an evident derangement of the digestive function, which may be regarded as a state not only most likely to generate local irritation, but to increase the diathesis favourable to Chorea. In this state of habit, mental emotions operating on the brain induce irregular action in the liver; and thence, in its morbid secretion, a source of local irritation is set up, perfectly adequate to the production of the disease.

The last exciting cause of Chorea which I shall mention, is one to which I have already alluded—I mean metastasis of Rheumatic Inflammation, when the inflammation is transferred to the thoracic viscera. In those cases which have come under my observation, death ensued in both instances; and, consequently, an opportunity was afforded of examining the state of the nerves. Whether any similar condition of the sheath of nerves, in a less degree, occurs in ordinary cases of Chorea, it is impossible for me to determine.

Under the impression that Chorea is a disease of debility, a course of active purgatives may appear to you to be contra-indicated; and, as a general rule, I should say that it is so; and that, if you regard the state of the bowels, and the disordered condition of the secretions, as the sole exciting cause of Chorea, and treat all cases with purgatives, I may venture to assure you that your expectations will, undoubtedly, be disappointed: nothing, believe me, has more retarded the progress of the healing art than uncontrolled and indiscriminate generalization. In numerous cases, however, purgatives must be regarded as your principal resource; and you will find, that instead of reducing still more a frame already apparently too debilitated, the strength of the patient will revive, and the command over the muscles be gradually re-established and confirmed by the steady adherence to the purgative plan. In those cases in which the alvine discharges are black, and exhale a very offensive odour, you cannot err in the frequent repetition of active cathartics. This is well exemplified in the case before us; the stools were of an unna-

tural dirty hue, and foetid; the effect of the purgatives in lessening the irregular movements was obvious; and although these still continue, yet they are considerably less violent, and rapidly abating. Where purgatives are obviously indicated, and when the result of their employment is the rapid abatement of the involuntary movements, you will usually observe that this is in the direct ratio of the improved complexion of the alvine discharges, and that as soon as these become natural, the disease is cured.

The use of purgatives in Chorea was known to Sydenham, although his treatment of the disease was founded on the absurd opinion that it depended on a humour thrown upon the nerves: he bled, employed purgatives freely, and gave tonics to strengthen the nervous system*. Few cases admit of the use of the lancet; but set this aside, and the treatment of Sydenham is exactly that which you will find most successful; that is, by the combination of the purgative with the invigorating plan of treatment. The great confidence which I repose in the work of Dr. Hamilton on Purgatives, backed by the evidence of Dr. Parr and others, led me for some time to place my sole reliance on cathartics in the treatment of Chorea; but frequent disappointments have proved to me, as they will to you, the folly of confiding too much to any one description of remedies. So greatly, however, are we governed by authority, that I have seen purgatives successively prescribed when the bowels were open, and when the evacuations presented the most natural aspect. I cannot, gentlemen, too urgently caution you to avoid yielding up your judgments to any authority, however high: the first duty of a physician is to think for himself. It is not my intention, however, to affirm that you are not to continue the use of purgatives when the symptoms remain unabated, or nearly so, merely because the evacuations have assumed a healthy character; but surely that ought to be a sufficient reason for believing, that whatever may have been the original exciting cause of the involuntary movements, when alvine irritation no longer exists, it is time to look for some other cause to explain their continuance. Nothing is more difficult, in forming our opinions of the origin of diseases, than to distinguish between cause and effect: the state of the intestinal contents may in many instances be the exciting cause, in others it is as likely to be the effect of the disease. The kind of purgatives to be employed is also of some importance. The nature of the suspected irritation will in part guide us: but besides clearing effec-

* "Indicationes eurativas primùm ad humores illos tam venæ-sectione, quam purgatione minuendos; dein ad corroborandum genus nervosum omnino dirigendus censebam."

Sydenham, *Opera Universa*. p. 495.

tually the bowels, it is to be kept in memory that purgatives may serve also the purposes of counter-irritants; and when congestions in the head are suspected, this is of more importance than the sweeping out of the intestinal canal. The stimulant effect of Calomel and Jalap, by augmenting the action of abdominal vessels, pours much fluid into the bowels, and by this method the circulating system is not merely locally, but generally unloaded.

Unless, in cases of metastasis, which even when Chorea is not the result, require the use of the lancet, the part of Sydenham's practice regarding blood-letting is not to be followed. Purgings, as long as any cause of irritation exists in the intestinal canal, should be continued, and even beyond this period, if cerebral congestion be suspected; but other means of depletion have generally proved injurious. One exception, however, to this rule must not be overlooked: when there is reason to suspect injury to the head from a fall, or a blow, previous to the appearance of the disease, then we shall find much advantage from that degree of local depletion which is always obtained from the introduction of a seton into the nape of the neck, in chronic affections of the brain, when organic mischief is going on. A proof of the advantages of a seton, in such a condition of the brain, is well illustrated by the benefit derived from it in one of the cases of Epilepsy to which I directed your attention, in my last lecture.

If purgatives have often failed when solely depended upon in curing cases of Chorea, tonics have not proved more useful when they have been administered without previously clearing the *primæ viæ*, or when they have been trusted to alone. It is evident, however, that the best method of insuring the cure after the topical acrimony has been removed, is to invigorate the constitution; and with this view various tonics, according to the fashion of the day, for there is a fashion in medicine as well as in dress, have been employed. You perceive that I have chosen the Carbonate of Iron for this purpose; and although you will find in the works of Dr. Good and others, that the preparations of iron have been found too stimulant, yet my experience does not warrant me to coincide in this opinion. The chief objection which has been offered to the use of the Carbonate is the great uncertainty of its operation, arising from the peroxidization of the Oxide of Iron, formed from the Sulphate, in the usual manner of preparing the Carbonate; and the small quantity of the real Carbonate contained in a large dose of the nominal Carbonate. By prescribing the Carbonate in the fluid form, at the moment of its formation, and in combination with the Chloride of Sodium, the tonic influence of

the Chalybeate is procured in its highest degree, whilst the Chloride aids its effect by keeping open the bowels. Some practitioners are in the habit of ordering the black Oxide of Iron, as a mild tonic, in combination with Rhubarb; but the extrication of Sulphuretted Hydrogen Gas, by the action of the Oxide on the fluid contents of the intestines, is an objection to this form of exhibiting Iron in Chorea.

In some instances, antispasmodics, particularly Camphor and Musk, have succeeded in curing Chorea; but more reliance, under ordinary circumstances, is to be placed upon a judicious course of purgatives, followed by tonics.

Melancholia.

Another case, gentlemen, connected with the nervous system—one of *Melancholia*—is at present under treatment, and well worthy of your utmost attention. The subject of it, Ann Rooke, ætatis 29, of a dry, spare habit, pale, sallow complexion, large veins, and black hair, which, as you know, are the characteristics of what is termed the melancholic temperament, was admitted a patient of this Dispensary on the 12th of November. She stated that about four months ago she suffered depression of spirits from some family matters, and has not since felt in her usual state of mind. She labours under a constant dread of some unfortunate event befalling her; and, to use her own expressions, "is utterly uncomfortable in her mind." Two months ago, there was a little abatement of this mental uneasiness, but it soon returned, and she is now truly miserable. Her bowels are irregular, and her urine is high coloured. She feels a dizziness, as if she were about to fall, a constant desire to change her place, and an acute pain in her head, which is augmented when she stoops. Her appetite is ravenous. The only medicine which she had taken, before her application at the Dispensary, was a little Camomile tea. She was ordered, by the house surgeon, to take two spoonfuls of a mixture of equal parts of the Aloetic decoction and the *Mistura Ferri*, twice a day, with four grains of Blue pill and the same quantity of extract of Henbane, every night, at bed-time.

On the 15th the blue pill was omitted, and five grains of Camphor and three of Extract of Henbane substituted for it; and on the 16th I saw her for the first time. She then complained of a burning pain at the top of her head, accompanied with the utmost depression of spirits; her sleep being short, and interrupted with frightful dreams. The bowels were confined, requiring the daily aid of purgatives; but she had not examined the aspect of the stools. The Catamenia has never been suspended; but, at the last period, the discharge was very scanty. She

was ordered to take that evening an emetic, consisting of ℞j. of Ipecacuanha powder and gr. i. of Tartrate of Antimony and Potassa; and after its operation to commence the use of the following mixture.

R Tincturæ Digitalis, f. 3j.
 Tincturæ Hyosciami, f. 3iij.
 Misturæ Camphoræ, f. ʒviijss. M.
 Sumantur cochl. iij. majora, 8va
 quâque horâ.

To-day she says that she feels considerably more calm in her mind. The emetic brought a quantity of sour matter off the stomach, and also purged her; but she has had no motion since. The stools were dark-coloured and fœtid, and the urine high-coloured. Her sleep is still imperfect and dreamy; and yesterday, from eleven o'clock in the forenoon until night, she suffered the most acute pain across the eyes. The pulse is 84, and soft; the tongue furred, and covered with red papillæ; and she has an unpleasant taste constantly present in the mouth. A fluid drachm of the Tincture of Digitalis was ordered to be added to her mixture, and she was directed to take gr. xij. of the Colocynth pill every night at bedtime.

Such is the state of this patient. I shall not, at this time, enter upon any explanation of the symptoms, but merely mention that the Foxglove is given with a view to its narcotic, not its diuretic influence.

GENERAL DISPENSARY.

Disease of the Hip, combined with Disease of the Knee; with Clinical Remarks,

By MR. COULSON.

ESTHER KEELAND, aged 21, of a fair complexion and strong constitution, was admitted at the General Dispensary, under the care of Mr. Coulson, for an affection of the left knee and hip. About a month ago, whilst sitting at work, she was seized with pain darting through the knee, and a slight swelling on either side of the joint. Pain has continued in the knee ever since, being always worse towards evening. She did not complain of the slightest pain in the hip. Suspecting, however, that the hip was affected, Mr. C. made pressure in front of the joint and behind the trochanter major. This gave her great pain, and the pain extended down the outer and front part of the thigh to the inside of the knee and insertion of the ligament of the patella. The knee is also exceedingly painful, and a quarter of an inch larger in circumference than the right one. Pressure made on the knee-joint gives pain, which extends down the shin to the front of the foot. Rotation of the femur against the acetabulum, and flexion of the

knee, produce pain. The patient limps, and walks with the toes pointing to the ground and a little turned outwards. Feels a stiffness, weariness, and numbness in the whole limb, particularly of a morning.

C. C. ad 3xvj. coxæ sinistræ. Mist. Aper.
 p. r. n.

Immediately after the cupping, she felt the numbness subside and the pain greatly diminished. She was ordered to keep on her back, and to avoid all motion of the limb. The cupping was repeated twice, and a blister applied over the hip. At the end of a fortnight from her admission she was discharged quite cured.

November 18th.—To-day Mr. Coulson made the following observations on this case, and disease of the hip in general.

Gentlemen, as disease of the hip (by which is commonly meant disease of the bones entering into the formation of the hip-joint, more particularly of the head of the femur) not unfrequently comes before our notice, I may, perhaps, advantageously draw your attention to the symptoms and treatment of this complaint. The disease commences with a stiffness of the limb, and a sense of fatigue and weakness after the slightest exertion; occasional darting pains down the thigh, and generally a peculiar pain at the knee;—sometimes there is pain in the hip itself, but frequently it is altogether wanting. The pain in the knee is often the only symptom which at first attracts the attention of the patient, and induces him to apply to a surgeon; the pain is also generally more severe during the night. The surgeon, on examination, finds the knee in most cases sound, although not invariably so; but if he presses in the neighbourhood of the hip-joint, either behind the trochanter major or in front, where the psoas magnus and iliacus internus pass over the articulation; or if he grasps the foot and rotates the head of the femur against the acetabulum, he soon ascertains that the hip is the seat of the disease. The weakness and stiffness which the patient at first experiences are soon succeeded by a limping gait, or a slight degree of lameness. But all these symptoms (and even the pain in the knee) are at first so slight as to be entirely neglected even by adults; and in young children, who have not the power of communicating their sensations, limping or lameness is the first symptom which attracts the notice of the parent, and, when observed, is too often referred to some other cause than that from which it proceeds.

It thus happens that the disease may exist for some time, both in adults and children, without being discovered. How long it may remain in this early stage, is, of course, uncertain; depending on the constitution and age of the individual, as well as a variety of other causes. The usual time,

however, is from one to six months. If the complaint be not arrested at this period, it goes into the next stage, which is marked by symptoms too evident to be mistaken or overlooked. The affected limb will be generally longer than the sound one; the trochanter major is directed more outwards than in the natural state; the nates of the affected side are flatter, the folds of the skin considerably deeper, and the whole limb, particularly the thigh, is thinner and more flabby. The surgeon may convince himself of these changes by submitting his patient to an accurate examination. In the first place, let me advise you to place your patient in the horizontal position on a flat hard substance, as the table or floor, and not on any soft yielding substance, as a bed or sofa, &c. because their yielding nature will prevent you from seeing accurately the deviation from the natural form of the parts. When you have put the person in this position, you will, in most cases, perceive the trochanter, the patella, and malleolus, lower than in the other, or sound limb. Then grasp the foot of the affected limb in your hand, and, placing the other hand on the knee, in this manner rotate the head of the femur against the acetabulum. The pain which the patient experiences from this particular mode of examination will soon apprise you of the mischief going on in the joint. Pressure in front of the joint, and just behind the trochanter, will confirm you in your opinion of the seat of the disease. After you have examined the patient in the horizontal position, direct him to stand up, and you will see that he does not rest equally on both feet. The sound limb is extended, whilst the affected one is bent; the knee being lower than that of the opposite side, and the foot generally everted, though it is occasionally turned inwards; and the nates also are flattened. The lengthening of the limb in this stage of the disease, is the most prominent symptom. Now you will be surprised when I tell you that there is scarcely no point connected with disease of the hip which has given rise to more discussion than the explanation of this symptom, some contending that there is no real lengthening, whilst others assert that the limb is itself actually longer than the other. Those who contend for the latter opinion conceive that the limb is actually lengthened, either by the expansion of the head of the bone, or by an increased secretion of the synovial fluid, or by matter pushing the limb downwards. It is certainly difficult to understand this explanation, when one considers how accurately the head of the femur is adapted to the acetabulum, and how little extension the capsular ligament is capable of allowing. Those who contend (and, I think, contend correctly) that there is no real lengthening, say, that "the apparent elongation is produced by the

position of the pelvis being altered, in such a way that the crista of one ilium is visibly depressed below the level of that of the other. It is easy to understand how this effect is produced, by observing the position in which the patient places himself when he stands erect. He supports the weight of his body on the sound limb, the hip and the knee of which are, in consequence, maintained in the state of extension; at the same time the opposite limb is inclined forward, and the foot on the side of the disease is placed on the ground, considerably anterior to the other, not for the purpose of supporting the superincumbent weight, but for that of keeping the person steady, and preserving the equilibrium. Of course this cannot be done without the pelvis on the same side being depressed. The inclination of the pelvis is necessarily attended with a lateral curvature of the spine; and hence it happens that one shoulder is higher than the other, and that the whole figure is in some degree distorted*." Sometimes in this stage of the complaint there is no lengthening of the limb; and the absence of this symptom depends, according to Rust†, on the co-existence of inflammation and caries of the acetabulum with disease of the head of the femur, so that the bones composing it will be pushed by the superincumbent weight of the body from above, and the pressure of the head of the femur from below, and in this manner the lengthening of the limb will be prevented. The surgeon, Rust says, may discover this peculiarity, which is of very seldom occurrence, by an accurate comparison of the sound with the diseased limb. The ilium of the affected side is higher, and often painfully swollen, the body inclines more to the side, and the distance of the trochanter from the upper part of the ilium, greater than in the sound joint.

The patient does not remain long in this condition; the pain at the knee, which was before slight, becomes very severe, and impedes every motion of the limb, particularly that of extension. This circumstance, combined with the fact of the pain in the hip attracting but little or no attention, occasionally deceives the practitioner, and in almost every case misleads the patient, as to the real seat of the disease. It sometimes happens that the knee is affected at the same time with the hip, as I think was the case in Esther Ketland. Ford‡ says that the knee, after the most minute examination, will be found in a perfect sound state; but this is too general an assertion, and not correct. Mr. Brodie examined a case where one half of the joints of the body were diseased. The pain of the knee, however, almost invariably

* Vide Brodie on Diseases of the Joints.

† Arthrokakologie oder über die Verrenkungen durch innere Bedingung, &c. von J. N. Rust. Vienna, 1817. P. 36.

‡ Ford on the Disease of the Hip-joint, p. 13.

attends the early stages of disease of the hip, and different explanations have been offered to account for its occurrence. It is generally believed that the pain is conveyed by the branches of the anterior crural nerve, down the thigh to the knee; but Sir C. Bell conceives that it is communicated by means of the obturator nerve. "The obturator nerve, as you know," he says, "passes through the thyroid foramen, down to the hip-joint, and after supplying the muscles is distributed upon the inner part of the knee. The nerve in its course is thus involved in the inflammation which affects the hip-joint, and the pain is referred to its extreme cutaneous branches, at a part distant from the seat of the disease." This explanation is not of itself sufficient to account for the symptom, for we very commonly find the pain extending along the middle and even outer part of the thigh, whilst the obturator nerve is distributed to the muscles on the inner side of the limb. It has struck me that, from the intimate connexion of the long head of the rectus femoris with the outer edge of the acetabulum, and with the capsular ligament, this muscle may take on the inflammatory action, and the pain in this way be conveyed down the limb to the thigh. We find something analogous to this in diseases of the shoulder-joint; the pain in these cases extends down the front of the arm to the insertion of the biceps, and the long head of the biceps, as you well know, in intimate connexion with the capsular ligament of the joint, and the glenoid ligament of the scapula. I will go no further with these speculations, but merely observe, that in all probability all the causes assigned, and others not yet discovered, have their share in producing this symptom, and that it is not to be explained by any one alone.

If the disease be not arrested at this stage, a new and most formidable set of symptoms supervene; the elongated limb becomes gradually, or what is often the case, suddenly shorter, so that on examination it is found one, two, or more inches shorter than the sound limb. This symptom generally depends on dislocation of the femur on the ilium. The head of the bone, as well as the capsular ligament, have been probably destroyed, and there being nothing to counteract the action of the extensors, the femur is drawn upwards. The nates, which were flat, or even flabby, become rounded or prominent, and swollen, and the toes are turned inwards. Sometimes the shortening occurs without dislocation of the femur having taken place. A case of this kind occurred to me some time ago in this institution. A girl of the name of Dexter, who had been for a long time under my care, died with disease of the hip in the most advanced stage; there was shortening of the limb, prominence of the nates, inversion of

the toes, and abscesses in the neighbourhood of the joint: all these symptoms led me to conclude, that there was dislocation of the head of the femur; but, on carefully examining the joint after death, I found the capsular ligament entire, and no dislocation. The head of the bone, and a great part of the neck, had been destroyed by caries, and in this way the shortening was produced without dislocation. There is shortening of the limb from another cause, to which I must call your attention, and of which the following explanation has been given by Sir C. Bell, in his *Clinical Observations on Diseases of the Hip-Joint**:—"The muscles in their action press the tendons against the inflamed parts, and hence it is that the patient cannot bear to lie with his limbs stretched straight along the bed, for this produces a tension on the front part of the joint. He inclines the body, therefore, and raises the knee upwards to the belly, bending or doubling himself in the most easy posture. In this way he twists the spine and inclines the pelvis, drawing it obliquely upwards on the affected side." This apparent will be easily distinguished from the real shortening of the limb; you should place your patient even on his back, and then bring the pelvis into a straight position, when you will find the limbs of both sides of equal length. It sometimes happens that the symptoms which have just been enumerated, as characterizing this stage of the complaint, do not present themselves, but a lengthening of the limb takes place, in consequence of the head of the bone being drawn forwards, downwards, and inwards, into the foramen ovale. When this occurs, you will find the limb three or four inches longer than the other, the knee bent, and the foot turned outwards, with the toes pointing to the ground. A prominence will be felt in the region of the groin, from the subjacent head of the thigh bone. Cases of this kind are extremely rare; I have never seen an instance of it in the living subject. In the museum of the College of Surgeons, there is a preparation, presented, I believe, by Sir C. Blicke, in which the head of the femur was dislocated, from the effects of disease, into the foramen ovale. Mr. Tyrrell mentions, in his *Surgical Course*, a case of this kind, which came under his notice; and Mr. Hicks, of Emsworth, had a case of this nature under his care, of which the following is an outline:—Master S. at nine years, in 1826, laboured under a severe affection of the hip, accompanied with great constitutional irritation. Matter formed in front of the joint, for the evacuation of which an opening was made. The wound continued to discharge for a long time, and pieces of bone occasionally came away. In the middle of August 1829, the child had a fresh attack

* Vid. *Medical Gazette*, vol. i. p. 78.

of the disease of the joint. On the 8th of October, he was examined by Mr. Hicks, who found the limb much elongated, the knee and foot turned outwards, and the head of the femur near or into the foramen ovale. By counter-irritants, rest, and attention to the general health, the complaint in the hip was arrested, and the child restored to perfect health; the deformity, of course, remains. With such extensive mischief going on in the interior of the joint, you will expect to find the neighbouring parts participating in the disease. This, however, is not invariably the case; for, in some instances, the disease will go through all its stages, and even dislocation or ankylosis occur, without any external suppuration taking place. But, in the majority of cases, the glands in the groin become enlarged and painful; matter forms near to the joint, more frequently on its outer side; and this is indicated by the tumefaction, and great pain of the part and severe rigors with which the patient is affected. If the patient be a delicate scrofulous person, the constitution suffers considerably in the advanced stage of the disease; there is great prostration of strength and emaciation of the whole body, with night sweats and hectic fever, and he not unfrequently falls a victim to the complaint. If, on the other hand, the patient is comparatively strong, the constitution suffers but little, and he recovers with no other mark of the disease than the deformity. During the progress of the disease, the motions of the limb become more and more impaired, but the power which the patient acquires of using the dislocated limb, after the disease has subsided, is very great. There is a female residing in this neighbourhood whose thigh bones are both dislocated from disease, and who can nevertheless walk about very well, without any pain and inconvenience to herself.

At our next meeting, I shall continue the subject of Disease of the Hip, and make some observations on the case of *Hæmatocele*, on which I operated yesterday.

CHOLERA MORBUS OF INDIA.

To the Editor of the London Medical Gazette.

Harwich, Nov. 12, 1831.

SIR,

HAVING had an opportunity of becoming familiar with the cholera morbus, as it prevailed at Calcutta in the year 1818, and subsequently having had frequent occasions of seeing and treating this disease during several years service in Ceylon, I presume to offer some few remarks on this malady, which I trust at the present period will not be deemed

uninteresting, or unacceptable. I shall be as concise as possible.

That the disease which has been ravaging the continent of Europe is contagious, I think admits not of a question; the manner in which it has been imported into this country at Sunderland, is a proof of this fact, unequivocal, indeed, except to those who will not be convinced; and there is every reason to believe that the cholera of Europe is identical with the cholera of India, as it was known there in 1817, and during subsequent years. Now it appears to me, that if we admit the fact, that the disease of Europe and that of India are one and the same, we must of necessity come to the conclusion that it has been brought from Hindostan to Europe by means of contagion alone; for on no other grounds can we reasonably account for the progress of this disease through every variety of climate and temperature; for, like the small-pox, the heat of the dog-days of India, and the cold of a Russian winter, are equally favourable to its existence.

After careful deliberation on the subject, and having reviewed numerous facts which occurred under my own observation, I am led to hazard the opinion that the fatal epidemic of India, which first made its appearance in 1817, was a contagious disease. By means of this quality it has pervaded almost every part of India: it has traversed Europe from east to west, and finally arrived in our own country.

The cholera morbus has long been known in India—perhaps for centuries; and in certain spots, particularly those otherwise unhealthy, it frequently proved fatal, like the ordinary autumnal cholera of this country; but whether the disease ever before appeared as an epidemic, previous to 1817, is more questionable. I am at least certain that it was a generally received opinion in Ceylon that the disease was unknown as an epidemic on the western coast of that island, and all felt secure (fallaciously, as the event proved) that it would not reach that part of Asia: and when the disease first broke out in Bengal, the medical officers considered it novel in its character, as it was more general in its progress, and more fatal in its effects. Unfortunately—I must so speak—the question of its being contagious was never duly investigated: one and all at that time attributed its origin to atmos-

pheric influence. Had more trouble been taken, and more attention paid to this subject, I cannot help thinking that we should have arrived at a very different conclusion.

To substantiate the views which I have here advanced, I would beg to relate a few facts, chiefly as connected with the appearance and progress of the disease in Ceylon.

If we trace the disease from its birth at Jessore in 1817, we shall find that it travelled frequently in opposition to a continual strong current of wind—namely, the monsoons, in the course of human footsteps, and of commercial intercourse, till at length, in the beginning of the year 1819, it reached that part of the Coromandel coast which is opposite to the island of Ceylon, from whence it was carried over to that island, and first made its appearance at Jaffnapatnam, the nearest town to the great continent of Hindostan, and the capital of a large commercial district, thickly inhabited. From Jaffnapatnam it was carried to Trincomalee, and getting on board the shipping, there is little reason to doubt but that through this means it was conveyed to the Mauritius. But to return: from Jaffna we also find it spreading southward to Colombo, the seat of government; and from thence eastward to Kandy, the old capital of the late King's dominions in Ceylon. In its progress to these places, it still observed the same laws, shewing itself only where human intercourse was constant and frequent, and where it had a succession of subjects for its propagation. At the period when the disease broke out in these towns, I was stationed at Korunegalle, distant from Colombo about sixty miles north-east, and from Kandy about thirty miles north-west. Korunegalle is the chief place in the Seven Korles, a province of from seventy to eighty miles long, and from thirty to forty miles wide, containing a population of eighty thousand souls, and garrisoned by about one hundred and fifty European, and from two hundred to three hundred (including pioneers) native troops, and is near the southern limits of the province. Within this district not a single case of cholera occurred to my knowledge, notwithstanding the disease raged along the whole line of its south and western boundary, on which human intercourse was frequent and constant, but we had little or no communication with either

Colombo or Kandy, and to that cause I now must attribute the circumstance of our escaping this complaint; separated as we were from our neighbours, by a broad belt of jungle on the west, and by a mountainous district on the south. One death only was reported to me during the prevalence of the cholera in the adjacent district. The individual was a native, and the symptoms, as related to me, were those of this disease. This man died at a place about twenty miles from Korunegalle, on the road to Colombo. The disease was at its height at Colombo during the month of April 1819, and was mostly confined to one company of the 83d regiment, forming the garrison. This company occupied a barrack near the main gate leading out of the fort into the Pettah, or native town, and separate from the barracks occupied by the rest of the regiment. The barracks at Colombo are small houses, in detached parts of the fort, each capable of containing one company only.

I could bring forward many more facts tending to confirm my argument, but the subject has been publicly and ably discussed: these which I have related are strong in favour of the opinion of the contagionists; for my own part, believing that the spasmodic cholera of India, which has now spread over nearly the whole of Europe, is a disease which, in its mode of propagation, possesses all the properties of a contagion, to maintain the contrary is wilfully to abandon the maxims of prudence, and to remain blind to the dictates of common sense.

In several cases of recovery from Indian cholera, which occurred under my own observation, I noticed that a favourable crisis in the disease was marked by the coming on of a profuse perspiration, the sweat literally pouring off the patients in streams; but I am not prepared to say whether this occurrence was only an accidental circumstance, depending upon the agency of a high degree of temperature operating on European constitutions, or whether it was one of nature's efforts for throwing off the disease. The knowledge of the fact may be useful in two ways—in directing us in the employment of remedies, and in devising the means of preservation from the disease; and explains the reason how the wearing of flannel next the skin, which was long believed

in India to be an effectual preservative against the cholera, acts in keeping off the attack of this malady. Dr. M'Whirter, who was presidency surgeon at Calcutta, and physician to the Marquis of Hastings, enjoying a most extensive private practice, first mentioned to me this fact, when the cholera at Calcutta was on the decline; stating that he had not known, up to that period, a single death to occur from the disease amongst those who had constantly worn flannel next the skin, as an article of dress; and my own observations corroborated this opinion. A different result may have attended the experience of others; but I am inclined to believe that this simple means is one of the best preservatives from this dreadful disorder.

Next to the general adoption of flannel clothing, it is desirable that the breakfast of light food should be taken immediately after rising, and before exposure to the cold morning air. We know that this is recommended as a preservative from all kinds of contagious disorders, particularly fevers of a typhoid character; and as I have known many individuals who, in India, habitually took a cup of coffee immediately on rising from bed, and who enjoyed an immunity from the cholera, I think the example well worthy of consideration in this country. I would beg to suggest that the dragoons of the army should each have a cup of coffee and a slice of bread each morning before going to early stable-duty; and I think the best effect would result. The expense would be very trifling, and, at all events, it would lessen their opportunities of indulging in intemperance, by disposing of a portion of their daily pay, which would otherwise be squandered in liquor, or some other vicious means of indulgence. Temperance cannot, at this crisis, be too strongly enjoined, nor cleanliness and ventilation too strictly enforced. Great attention should be paid to the soldiers' messing, and in their duties great discretion should be observed. Unnecessary exposure to cold and wet should, as much as possible, be avoided; and when unavoidable, the means of an early change of wet for dry clothes should, if possible, be afforded, and its necessity urgently enforced.

The high state of discipline which our army has arrived at; the care and attention of its superior officers; and the means of a strict quarantine, which

every regiment in the service possesses in a particularly favourable degree; are, I trust, sufficient to lead us to hope, that this disease will not prove so dreadful a scourge amongst our soldiers as there is but too much reason to believe it has been on the continent of Europe, particularly amongst the lower classes of society.

In presenting these remarks, hastily put together, I am actuated only by a wish to contribute to the public good, and, with this apology,

I remain, sir,

Your most obedient, humble servant,
WILLIAM KNOTT,
Surgeon, 6th Dragoons.

PATHOLOGY OF CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

M. DE JONNES, whose very interesting work on cholera is referred to in the last number of the *Quarterly Review*, gives the following summary of the results of his observations on the pathology of that disease.

As his views are clear, and his inquiries have been laborious, you may perhaps think this extract worthy of a place in your miscellany.

I am, sir,

Your very obedient servant,
C. W. CROWDY.

Brixton Hill, Nov. 16, 1831.

1st. This malady has many symptoms in common with the cholera morbus of our climates, and it has thence derived its name; but it has others peculiar to itself, and which, joined to the mode of its propagation, and the violence and rapidity of its effects, constitute a malady *sui generis*, and one of the most disastrous recorded in the history of the world.

2d. Its characters are perfectly similar, or analogous, at points two thousand leagues distant, and in countries situated under the equator, or near the polar circle—in the interior of a continent, or on the sea-shore—at the level of the ocean, or in the mid region of the atmosphere.

3d. Contrary to epidemic diseases, which depend on heat, humidity, and marsh exhalations, and appear at particular seasons, this manifests itself at all

times, although heat is most favourable to its propagation.

4th. Its symptoms are regular, successive, everywhere similar, whilst those of epidemics vary according to the energy of the agents which give rise to them, and are constantly differing in intensity, form, and rapidity, sometimes even exhibiting phenomena which constitute another species of malady.

5th. Its principal symptoms are vomitings and purgings of a fluid kind, and in prodigious quantity; cramps and violent spasms of the extremities, great pain of the epigastrium, inflammation of the stomach and intestines,—symptoms greatly resembling those of poisoning.

6th. The principle of the cholera is the same in Europe, Africa, and Asia, since it produces every where the same series of external symptoms and internal lesions—in short, the same disease, since it similarly attacks every where all persons, whatever their sex, age, or race, and since it is neither modified by difference of place, time, or individuals.

7th. At the commencement, in the middle, and at the end of each irruption, it has the same degree of virulence, since it produces the same symptoms, and destroys those attacked by it with equal rapidity and violence. Its decline is shewn only by diminished power of propagation.

8th. Its germ is the most quickly active of all the varieties of contagion, for the deadly effect is sometimes almost immediate, though generally forty-eight hours intervene between the period of infection and the appearance of the first symptoms. We know that yellow fever may remain latent twenty days, small-pox sixteen, the plague thirty, and even more, hydrophobia three months and a half, &c.

9th. It has not yet been ascertained by observation, to what period we must limit the giving out of the morbid material, whether concrete or in vapour, which produces the contagion. From the rapidity of the malady this period must be very short, but it is probable that it commences with the appearance of the first symptoms.

10th. This rapidity of the phenomena of cholera constitutes this malady an *acute contagion*; whilst the plague, yellow fever, small-pox, measles, hydrophobia, also leprosy, (lespians*?) sy-

philis, the itch, may be considered chronic contagions.

11th. Like the maladies of the first of these classes, cholera generally attacks but once the same individual; the contrary, at least, is rare, and has not been well established. This immunity of persons, who have been once infected, from contagions to which they are exposed afresh, seems to result from an alteration in the absorbent system, which, in consequence of these maladies, becomes less susceptible, or ceases to be so altogether. A similar result is produced by living in prisons, or hospitals, or the habitual use of certain poisonous substances.

12th. The degree of aptitude for receiving this malady differs infinitely according to constitution, age, sex, diet, morals, circumstances of life, which may increase or diminish, as their effects may be permanent or transient, the absorbent power of the organic tissues, with which the germ of the contagion comes in contact.

13th. From these physiological differences it happens that, out of twenty persons exposed to the cholera, one only may receive the infection. It has also been ascertained from numerous observations, that out of twenty-five individuals bitten by mad dogs, one only became hydrophobic.

14th. It follows also, that there are more chances of escape from this malady for women and children than for men, for those who are weak than for the strong, during winter than in the summer, and especially with courage and resignation rather than being under the influence of dejection and fear.

15th. We are entirely ignorant whether the germ of the malady is introduced into the body by cutaneous or pulmonary absorption, or by the organs of nutrition. Anatomical examination seems to indicate the latter channel, since it demonstrates the seat of the cholera as in the stomach and bowels; but, on the other hand, from seeing the disease propagated with unheard-of rapidity among the population of India, who are unclothed, it would seem probable that the malady is received through the medium of the skin. However, observers have admitted as a preferable conjecture, that the germ of the cholera exists in gaseous emanations from the bodies of the sick, and that, consequently,

* Probably les piens, see Aliberl, &c.—ED. GAZ.

the respiration is the channel through which it is transmitted.

16th. It is probable that this morbid gerin, which re-produces itself in the human body by the assimilative action of the vital powers, acts at first with more or less violence according to its concentration and peculiar energy, which, perhaps, is dependent on its specific quantity.

17th. No circumstance warrants the supposition that it can be transmitted, in the open air, beyond the distance of some feet; and it is certain that there is no foundation for the assertion, that it can be transported from place to place by the currents of the atmosphere.

18th. But in places where the air is stagnant, such as the mid-decks of a ship, the wards of most hospitals, in barracks, the interior of houses, especially in large towns, the germs of the cholera accumulate, become attached to persons and things, and propagate the disease through the one mode or the other.

19th. The cholera breaks out wherever its germs are carried, which is the characteristic of contagious maladies; whilst epidemics appear only in certain localities, or certain countries, where their primitive causes exist.

20th. Finally, the origin and intimate nature of these germs are entirely unknown, as are those of the contagions which have been spread over Europe from time immemorial, and which daily occur to our observation. Experience and study have taught us nothing concerning them, and they must be ranked among those mysteries of nature which science cannot develop.

CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

I SUBMIT the following considerations to your decision, whether or not they are worthy a place in your useful and excellent journal: I have been led to them from seeing the daily publication of articles about the contagious or non-contagious nature of cholera, which are in many instances quite vague, and even contradictory, in consequence of no definite and universally-received meaning being attached to the term *contagion*;

209.—IX.

scarcely any two writers, probably, taking precisely the same view of, or attaching the same meaning to the word. Never has this, I think, been more strikingly manifested, than in the report circulated through the daily papers of the recent discussion in the Westminster Medical Society. I defy any one to glean from it any information on the debated point; and how should they, since it is evident that different views were taken by the different speakers, of the meaning of the term which they wished to attach to, or sever from, the disease in question? One doctor denies *in toto* that the disease is contagious, but thinks "that it may be *communicated* under certain circumstances." In the published statements of Drs. Russell and Barry, these gentlemen consider "that the germs of the disease were diffused, and the disease propagated, in two ways, one of which may be called *personal*, by the dispersion over the whole city of several thousand passengers and boatmen, who had come from infected places, or been exposed to infection on the passage or on board these vessels; the other, which may be termed *atmospheric*, by emanations from the barques and their contents, suspended in and carried by currents of air to susceptible persons, *independent of direct communication*." It appears to me that here a distinction is made where no difference exists. The first way mentioned, in which the disease was propagated, was as much atmospheric as the other; the two ways were, in fact, one and the same; for from whence did the "persons" who communicated the disease in the first way, obtain its germs? and whence did "the barques and their contents," which communicated it in the second way, obtain their germs? both of them, of course, from individuals who had laboured under the disease. And was it not as much through the atmosphere that the poison was conveyed from the crew and passengers of the vessels, as from the vessels themselves and their contents. It was likewise equally "independent of direct communication" in the one case as the other, for there was the intermedium of the crew and passengers (excepting the individuals among them who actually had the disease) on the one hand, and that of the vessels and contents on the other. Both received the infection from diseased persons, and

X

both communicated it through the medium of the atmosphere.

The terms contagion and infection are now, for the most part, used indiscriminately; the latter, in fact, being seldom employed. This I deprecate, for I think the distinction is useful; and the one, which I have adopted, appears to me the most classical, and least likely to occasion confusion. Whether, however, this be conceded or not, it will not affect the utility of these observations.

I would understand, then, first, by "*a contagious disease*," one which *requires*, for its propagation, that some part of the diseased person should, in one way or another, come into *actual contact* with some part of the healthy person. Examples of this are, syphilis, the itch, and other cutaneous diseases. Perhaps, hydrophobia may be ranked among them. By "*an infectious disease*," I mean one which is propagated through the medium of the atmosphere conveying exhalations, *whether directly or remotely*, whether more or less diluted, from a person or persons while labouring under that disease. I adduce some as certain, others as doubtful, examples of such diseases; doubtful, because medical men differ as to the way in which they may be propagated. The *certain* are, small-pox, measles, scarlatina, hooping-cough, the plague, &c.; the *doubtful*, typhus fever, cholera morbus, puerperal fever, erysipelas, &c.

A sporadic disease is one whose attacks are confined to one or to a few individuals, at any particular time or season; being independent of infection, and arising, for the most part, from accidental circumstances, such as exposure to cold, damp, &c. and may be instanced by a person suffering inflammation of the lungs, bowels, &c. from this cause. Under this class, I think we frequently find the diseases which I have placed as "*doubtful*" among the infectious diseases.

An epidemic disease is one which is propagated through the medium of the atmosphere, independently of the sources of infectious diseases, or of marsh miasmata.

The peculiarities attending diseases arising from marsh miasm, and other epidemics, I need not particularise.

Connected with these definitions, I would just offer one or two remarks, some of which have been recently sug-

gested to your readers in an article from Mr. Barham, of Exeter.

There seems to be no reason why two of the above sources of disease may not operate together. Suppose, for example, a sporadic case of typhus fever; as such, *per se*, not infectious: but let it occur in a thickly-populated and ill-ventilated part of a large town, with other circumstances to aggravate the disease, may not a specific poison be thus generated, which shall infect the air, and through it communicate the same disease to others?

The same may be asked with respect to an epidemic. May not a disease, which is originally an epidemic, and in its general course follows the laws of an epidemic, occurring under similar circumstances with those just supposed, be furnished with additional power by a specific animal effluvium, and thus have infection added to its means of being propagated?

With respect to cholera, it seems not impossible that the latter may be the way in which it is propagated, though I confess I feel little doubt myself that it follows exclusively the laws of infection.

One word with respect to quarantine. Though I should strenuously advocate its adoption, I am by no means prepared to allow that, (supposing the disease to be strictly infectious,) its most rigid observance would *certainly* keep the enemy at bay, if, as I see no reason to doubt, the infected air is capable of extending to any considerable distance. Allowing this, it no longer will remain matter of surprise to the advocate for infection, that this malignant disease should in some instances have spread in spite of quarantine regulations.—I remain, sir,

Your obedient, humble servant,

CHARLES P. SLATER.

Bath, Nov. 15, 1831.

CHOLERA—IS IT CONTAGIOUS?

By DAVID BADHAM, M.B. OXON.

Glasgow College, Tuesday, Nov. 15, 1831.

THE numerous facts that have been adduced by the contagionist party on the one hand, and the non-contagionists on the other, are of such a conclusive kind

in either case as to leave no doubt upon the minds of many that cholera both is and is not an infectious disease. Nothing renders this more probable to my mind than the mutual retraction of opinion that has prevailed among several medical men of observation and experience who, starting with the conviction of its contagious or non-contagious character, have subsequently seen reason for adopting a conclusion the very opposite of that with which they had set out. Now if we admit that both parties are correct in the statement of facts, how can such apparent differences in opinion be adjusted? or admitting all the statements indifferently as facts, to what circumstances is it attributable that cholera spreads in some instances with such fearful velocity from person to person, while at others it appears scarcely to take the character of a contagious disease?

The only way I can see of reconciling the dissension which at present prevails respecting the mode of propagation of this disease, is to suppose, that when cholera first makes its appearance, while it occurs as yet but in a few sporadic cases, and in different parts of a town or district, it is highly contagious and speedily diffusive, because the full effects of its noxious influence fall suddenly upon untried constitutions; but when the distemper is become epidemic, when the fomites of contagion have become very extensively multiplied, and when the very atmosphere has become charged with seeds of the disease, then it is that those who have hitherto escaped the contagion are on that very account exempted in a measure from the risk which had otherwise attended a nearer approximation to the infected; as the beginning with small doses of any poison will enable a person eventually to receive into his system even a considerable quantity with impunity. Hence the immunity of many in infected towns, whose susceptibility to the disease gradually decreases, while the air around them is continually deteriorating, till at last they can approach with impunity to the bed-side of the infected with comparatively little fear or danger. But this immunity, however general it may become from the above and other causes, does not prove the disease to be non-contagious; and, indeed, if healthy individuals with untried constitutions, and who had been living in a purer air, were

suddenly brought into close proximity with the disease, they would in all probability imbibe the contagion, and disseminate it to others similarly circumstanced to what they had been previous to exposure.

NOTE.—It is usually stated that the miasm of contagion is confined to a very limited sphere of action, varying in different diseases, but rarely extending many feet beyond the individual infected. I have, however, ventured to assume that such miasm may be greatly diffused, so as even to affect the whole atmosphere of a town, and in proportion to the malignity with which the epidemic may be raging. This appears to me probable—1, from one very presumable quality of such infecting agent which, as it must be extremely subtle, must be proportionably liable to almost indefinite dispersion, for even solid matter is almost indefinitely diffusible if it be diffusible at all in fluids: hence the operation of the finest chemical tests. 2. From the ascertained quality of a capacity in such infectious agents, that what can be concentrated till it acquires the fatal activity almost of prussic acid, may also be diluted down to harmlessness. Now the sudden deaths that have occurred during pestilences to persons in the act of unpacking merchandise, are generally admitted to arise from the over-powering activity of the concentrated form in which the miasm has made its attack. 3. Lastly, why but for this reason are persons who live in an infected town subject, as it has been remarked, to unwonted general indisposition of an indefinite character, and often so considerable and of such a kind as to need but a slight aggravation of symptoms to bring on the very epidemic that is prevailing? I conceive this to arise, because the air is to a certain extent corrupted by the diffusion of the epidemic poison, though not in all cases sufficiently so to induce the epidemic itself, but, in place of it, engendering other complaints, whose type and severity is proportioned to the susceptibility of the individual, and the dilution, so to speak, of the poison.

CHOLERA.

To the Editor of the London Medical Gazette.

Brighton, Nov. 22, 1831.

SIR,

IN consequence of Dr. Copland's allusion to my remarks on cholera, which you were pleased to insert in number 206 of your Gazette, I think it necessary to state that I did not see his article in the Foreign Quarterly Review, but that I am aware part of the treatment I proposed had been previously recommended.

The following queries having offered themselves to me, I beg leave to subjoin them:—

1. The depressing effects of the south-east wind (the scirocco of Italy) which have, probably correctly, been attributed to some electrical peculiarity, being more or less experienced in every climate, is there any connexion to be traced between this circumstance and the fact that pestilential cholera, comparing the point from whence it started with its present station, has upon the whole pursued a north-west track, accounting for the numerous deviations from it by lateral propagation by means of the various vehicles of infection?

2. Are there any data which tend either to overturn or to support the hypothesis that this epidemic is caused by a change in the electrical constitution of the atmosphere; that the expression used by some, comparing the state of the patient to that of an "exhausted Leyden jar," possibly may convey an important truth, and that electricity or galvanism, judiciously employed, may prove a most useful remedy? Galvanism would, moreover, seem suited, from the relation which exists between it and the nervous, especially the secreting power, and from the restoration of the secretions, particularly that of the kidneys, being of the first importance.

To revert once more to the question of contagion. Though we must concede to the non-contagionists, that this epidemic, as well as lues, plague, &c. not being coeval with man, the first case of those diseases which ever occurred *must* have been sporadic, and have arisen from other causes than contagion; and if this happened once, it may again at any time: still I do not see how any

one can deny that this and many other diseases may, under certain circumstances, become infectious, or doubt, at this time of day, that cholera has long since assumed that character, and at present is chiefly propagated by contagion. Since, however, ocular proof of actual transmission from one individual to another cannot be procured and conviction cannot be forced on any one, the discussion of this subject will now, I hope, give way to topics more immediately connected with the treatment of the disease.

By inserting the above, and noticing the errata* at foot, you will oblige me.

I remain, sir,

Your most obedient servant,

E. STANLEY, M.D.

ORIGIN OF THE VARIOLÆ VACCINÆ.

To the Editor of the London Medical Gazette.

SIR,

I TRUST to your sense of justice to give insertion to the following statement. All who have read your number for November the 5th, will immediately perceive the object I have in view. As my design is to be brief, I will deliver what I at present have to say in as few words as possible.

The history of the origin of the variolæ vaccinæ, divested of all ambiguity and confusion, stands thus. Dr. Jenner found that a disorder caught from horses and cows in the dairies of Gloucestershire, prevented persons so affected from being liable to small-pox. After long and patient, and successful investigation, he came to the conclusion that the disease so caught was a mild variety of the variolæ which attacked men. This belief afforded him the means of unraveling all the difficulties connected with the practice of the cow-pox inoculation, and ultimately to present to the world the most comprehensive and perfect specimen of medical investigation that has ever been witnessed. I say this without fear of contradiction, inasmuch as scarcely one fact connected

* In No. 206, p. 176, line 21, for "embrocations," read "liniments;" line 28, for "counter-indicated," read "contra-indicated;" line 30, for "venæ," read "vena;" line 40, for "oxide," read "oxyde."

with the nature or modifications of the disease has been recorded of which he was not aware.

His opinions concerning the origin of the disease necessarily rested upon a different foundation, and could not, therefore, be so conclusive as those which were based on fact and observation. He conceived that the variolæ, in all their forms, were ultimately to be traced to the horse. I need not remind your readers how much he was ridiculed for this and many of his other doctrines, but there was a foundation for them that they little dreamt of.

Matters continued in this state of uncertainty up to the period of his death, with this additional difficulty, that there was an increasing unwillingness in the minds of medical men to subscribe to many of Dr. Jenner's most important positions. Since that period, the great problem touching the origin of the variolæ vaccinæ has been solved, and the soundness of Dr. Jenner's views has received the most signal corroboration.

I am not aware that the facts that I am about to state, were ever before the period alluded to brought to bear on the origin of cow-pox, and on the identity of that disease with small-pox; but be that as it may, it has been incontestibly shewn.

First, that cows in many parts of Europe have long been known to be liable to *small-pox*.

Secondly, that this disease has spread from flock to flock in the most fatal and pestilential manner.

Thirdly, that it raged in England not much more than fifty years ago, and that the practice of inoculation was had recourse to, to subdue its violence.

Fourthly, that it is even now occasionally a violent and fatal disease among the cows, and for the most part is propagated by contagion through the whole herd, when it breaks out in a dairy.

With the exception of the last fact, I believe every one of the above-named particulars were *hid* from the profession till within these four years. At least I do not know that the slightest reference has been made to them by any writer anterior to that time, in order to demonstrate the nature and origin of the variolæ vaccinæ. Their application to this subject is clear and conclusive. Dr. Jenner finds the remains of a more vio-

lent epizootic small-pox in his neighbourhood. Without being aware of the actual history of this malady in the inferior animals, he investigates its nature with matchless success, communicates it by inoculation to man, and affirms that the disease thus communicated will afford protection against small-pox as complete as that disease itself does.

What was the ground of this confidence?—*His conviction of the identity of small-pox and cow-pox*. On what was that conviction founded?—*Analogy, and the ascertained peculiarities of the disease*. How has this conviction been strengthened and demonstrated?—*By tracing the small-pox in cows for hundreds of years*, and affording the strongest presumptive evidence that the disease was sometimes communicated to man, in its most fatal form, as it has likewise been done in the mildest form!

It is very painful for me to be compelled thus to address you, and still more that I should find it necessary at this late period to refer to a work of my own for proofs of the accuracy of these statements. The interesting fact recorded by Dr. Sonderland is demonstrative of the truth of the conclusions which have been mentioned, though some of his inferences are at variance with the best historical evidence.

I know that when an author complains he is generally supposed to be impelled by over-weening conceit or mortified self-love. I am not, I trust, one of that class. I value truth and justice above all things; and provided they are duly upheld, all personal feelings would instantly give way. On this occasion I am satisfied that I am not seeking too much from you, or from your contemporary who first published the document to which this letter refers, when I beg that you will honestly and faithfully compare it with my published work; and having done so, I would ask you, or any competent judge, whether it was right and becoming to withhold all the evidence which that work contains?—I am, sir,

—Your obedient humble servant,
JOHN BARON.

Gloucester, Nov. 21, 1831.

SMALL-POX.

To the Editor of the London Medical Gazette.

SIR,

THE spirit of your Journal seems so fair, and your desire to maintain the truth is so manifest, that I feel assured you will permit me to make a few remarks upon a paper that appeared in your last number, although it has been avowedly taken from the publication of a contemporary.

I believe it to be a mistake to affirm that the variolæ vaccinae have originated in the manner referred to in the seventh aphorism of Doctor Sonderland. It is at least certain that one of the earliest and most authentic historical documents, which by the best judges has been pronounced to be descriptive of the small-pox in man, proves that the same disease simultaneously appeared in the inferior animals. But, be this as it may, traces of eruptive epizootic diseases, in many cases communicated to man, may be found in the historians of almost every age. As we descend nearer to our own times, the descriptions are more precise and accurate; and the variolæ among cattle is a disease as clearly described, and as accurately defined as any variolæ that ever attacked man. And it is a most remarkable fact, that in the year 1690 it began with the animals, and immediately afterwards proceeded to attack the human species in the most fatal form. It is little more than fifty years since this epizootic pestilence ravaged the cows of a large portion of Europe, and especially this country; and it has been proved, as far as any thing of that kind can be proved, that the cow-pox which Dr. Jenner met with in our dairies was the local, or rather *enzootic* remains of that pestilence.

I believe, sir, it is equally a mistake that the variolæ which appears among cows is always of the mild character that it has lately assumed, as is implied in the sixth aphorism of Doctor Sonderland.

During the last epizootic among the cows in this country it was of a most virulent and contagious character; and the practice of inoculation was frequently and successfully employed, as in the human subject, to subdue its severity. It is equally true, that the dis-

ease has, within these few years, been so violent in the dairies of Gloucestershire as to destroy the life of the animal, a case of which kind has been published in the Life of Doctor Jenner, page 351. The disease, likewise, when caught by the milkers, is often a severe one; and at times there is a considerable eruption. Were I to detail all the facts by which these statements may be proved, I should more than fill your number. They, and a great many others, have been examined, and arranged for the express purpose of proving the identity of small-pox and cow-pox, and thereby explaining the protecting virtues of the latter. The whole will be found in the fifth, and other chapters of the volume above cited. I have examined the evidence therein contained with great attention; and it appears to me as conclusive as any thing of the kind can be. The propagation of the small-pox to the cow, in the manner described by Doctor Sonderland, is an interesting and important fact, and affords the strongest confirmation of the accuracy of the doctrines contained in Dr. Baron's work.

I am, Sir,

Your obedient servant,

NON NEMO.

PHYSIOLOGICAL CONJECTURES.

No. II.

BY PHILEATHES.

To the Editor of the London Medical Gazette.

SIR,

I.

IT has long been an interesting question to determine, what is the precise state of the circulation and of the respiration, during the state of torpor in hibernating animals.

I think this may be done, in regard to the circulation, by submitting the web of the frog, the wing of the bat, the ear of the dormouse, to be viewed in the microscope.

I think the quantity of respiration may be readily and accurately determined, in the manner described in my former communication, in the Medical Gazette, No. 185, page 373.

It will be interesting to associate with these circumstances the state of the temperature, taken by a fine and delicate thermometer, in the axilla pressed by the wings of the bat, or the anterior extremity of the dormouse.

It appears probable that one character of hybernation is, in fact, that of a reduced state of existence, the animal being deprived, by the influence of cold, of the energy of part of the nervous system, and so brought lower down in the zoological scale.

Might it not, under these circumstances, bear to have these parts of the nervous system, viz. the brain, medulla oblongata, and medulla spinalis, removed, without the destruction of the function of circulation, as is observed, under peculiar circumstances, in the batrachia?

In fine, is not the case of the animal, in the state of hybernation, identical with that of an animal deprived of brain and spinal marrow? Does not cold slowly destroy the functions of these organs, whilst the experiment removes the organs themselves?—and does not the difference between the two cases arise from the different degrees of slowness or rapidity with which the influence of the brain and medullæ is removed?

A comparison between the remaining functions seems to confirm this conjecture.

II.

It appears probable that the peculiarities of the fœtal life consist also in those of a lower order of existence.

The blood of the fœtus is not only different from that of the parent, but, according to MM. Prevost and Dumas, its globules are larger—that is, it bears the character of that of an animal of a lower order.

There is also a remarkable deficiency in the function of respiration. The changes effected in the placenta, the organs of fœtal respiration (see Phil. Trans. for 1810, p. 213—217), are far less marked than those afterwards induced in the lungs.

Lastly, the fœtus bears to be deprived of the influence of the brain and spinal marrow without experiencing any impediment to growth and development. These organs may actually be destroyed, in the chick, on the third day of incubation, according to M. Serres, without arresting the growth of the animal.

Both in the hybernating and fœtus states, the peculiarity probably consists in a good circulation, with its secretions, and an independence of the large nervous masses and of respiration, in a greater or less degree; and both may thus be compared to that of an animal deprived of brain and the medullæ, whilst both probably bear to be deprived of these organs.

The general principle is that of a lower grade of animal existence.

PHILALETHES.

PROVINCIAL SCHOOLS OF MEDICINE AND SURGERY.

To the Editor of the London Medical Gazette.

SIR,

AMONG the schools instituted for the promulgation of medical and surgical information, the provincial establishments, in county and other large towns, do not seem either to have attracted that degree of attention in their respective districts, to which their means of furnishing information entitle them, or to have acquired, in the eyes of the profession, an importance proportioned to their real utility in promoting the education of the junior branches of the profession.

The subject has been enforced on my attention by a recent visit to one of our large provincial towns, Kingston upon Hull, in Yorkshire, where an Anatomical and Medical School has lately been established under the promising auspices of Dr. Alderson and his able colleagues. At present, the number of attending pupils is limited, owing, probably, to that temporary opposition which a newly-established institution generally meets with; but its ultimate success is ensured by the enterprise, experience, and talent, that are combined in the professors of the respective departments. Mr. Craven did me the honour to give a lecture on anatomy, that I might judge of the mode in which the anatomical department was conducted; and, if this school may be allowed to afford a fair criterion of other provincial institutions of the same kind, their object of giving a sound elementary education to the

young student cannot fail to be attained, and their utility in forwarding the means of education cannot be questioned.

The advantages which they present are numerous; not only to the student, who may be desirous of obtaining information, but to all concerned, whether in the business of medical instruction, or in the management of the hospitals and infirmaries which most of our large towns possess.

The labour of teaching is not confined to the mere act of delivering a lecture at stated periods; but his duties entail upon a professor the necessity of preparing himself by obtaining an intimate knowledge of his subject. The physician or surgeon, who is engaged in teaching, is compelled to instruct himself before he can instruct others; the advantage, therefore, derived from teaching is not confined to the pupil, but extends itself to the teacher, by holding out an additional motive to labour and study. With this view, his mind must be constantly directed to the cases of disease which he witnesses—his memory must be stored with valuable facts and observations—and he is obliged to keep pace with the progress of science, by reading the best works as they issue from the press. A man with his whole mind thus directed to the duties of his profession, becomes an acquisition of no ordinary importance to the town in which he resides; the whole population feels the effect of his information and experience; the poor in the infirmary have the benefit of his superior skill and judgment; and the lustre, which he has been enabled to throw around his own character, is thus reflected in the more solid advantages, which his medical and surgical skill confer on his fellow townsmen. It becomes, therefore, the interest, no less than it is the duty, of the governors of provincial hospitals and infirmaries to foster with care these rising institutions, which have difficulties enough to encounter in the hitherto insurmountable prejudices of the vulgar, without meeting with opposition from those whom they naturally look up to for support.

Indeed, in giving encouragement to provincial schools of anatomy, the governors of medical institutions are incessantly calling into action talents which might otherwise have been dormant, and are bringing forward as teachers men of industry and ability, who, from

neglect and want of opportunity, might for ever have remained unknown and unnoticed. From among these young men, the governors have the power of selecting the most distinguished and the best informed for the medical officers of these hospitals; thus rewarding merit and encouraging rising talent, instead of conferring the appointments on persons whose character is wholly unknown, except to a few immediate and interested friends of the candidate. The best talent, which the town affords, will be thus secured to the public institutions for the sick poor; or, if it be not secured, at least no plan can be well devised, that affords a fairer chance of advancement to the successful and industrious teacher of his profession, or that more effectually directs patronage to its legitimate object—the protection and advancement of merit.

Much, however, as all classes are benefited by such establishments, none participate in their advantages so deeply and so immediately as the students themselves. The regulations for study, now imposed on a medical student, by the recent enactments of the College of Surgeons and the Apothecaries' Hall, render it no easy task for a pupil, however diligent he may be, to follow, with any lasting effect, the course of study prescribed, in the short period allotted for their residence in town.

It is far from my intention to impugn the propriety, much less the motives, of their regulations; for, I believe, that these legislative bodies are impressed with a sincere conviction of the necessity of improving and extending the system of medical education, and that they are conscientiously endeavouring to attain this end by the enforcement of certain laws. But it is equally the duty of these bodies to have some consideration for the student, and to be aware, what an immense mass of labour they entail upon a pupil, who is desirous of fulfilling his duty to them, and his duty to himself, (duties not always identified in a pupil's mind,) by compelling him to attend all the lectures, not within the space of two years, but of two winter seasons. As it is some time since the pupillage of the Examiners of Apothecaries' Hall elapsed, in order to refresh their memories, as to what a pupil is enjoined to attend, and to give the latter some idea of the extent of pursuits he has to encounter,

when he comes to town, I subjoin a copy of our printed list of the hours of attendance on the various lectures, &c. delivered every week at Guy's Hospital:

	<i>Hours.</i>	M	T	W	Th	F	S
Lectures on Midwifery	$\frac{1}{4}$ before 8	—	—	—	—	—	—
— Chemistry	$\frac{1}{4}$ before 10	—	—	—	—	—	—
Examination of Patients for Admission	10	—	—	—	—	—	—
Demonstrations in Anatomy ..	11	—	—	—	—	—	—
Dressing casual Patients at Surgery	11	—	—	—	—	—	—
Prescribing for Out-patients—Assistant Physician } and Assistant Surgeon	11	—	—	—	—	—	—
Accidents, &c. attended by the Surgeons	at all hours	—	—	—	—	—	—
Surgeon for the Week attends in the Wards	12	—	—	—	—	—	—
Patients visited in the Wards by Surgeons	12	—	—	—	—	—	—
Physicians	12	—	—	—	—	—	—
Eye Infirmary	12	—	—	—	—	—	—
Surgeon Dentist visits	$\frac{1}{2}$ past 12	—	—	—	—	—	—
Demonstrations in Morbid Anatomy	1	—	—	—	—	—	—
Consulting Surgeon visits	—	—	—	—	—	—	—
Dressing the Patients finished at	2	—	—	—	—	—	—
Lecture on Anatomy	2	—	—	—	—	—	—
— Theory and Practice of Medicine	$\frac{1}{2}$ past 3	—	—	—	—	—	—
— Medical Jurisprudence	do.	—	—	—	—	—	—
— Botany and Entomology	do.	—	—	—	—	—	—
— Experimental Philosophy ..	6	—	—	—	—	—	—
— Comparative Anatomy	6	—	—	—	—	—	—

— Materia Medica	7	—	—	—	—	—	—
Physical Society	7	—	—	—	—	—	—
Lecture on Surgery	8	—	—	—	—	—	—

To follow with zeal so extensive a range of pursuits as is comprised in the above list, requires not only a spirit, but a frame of constitution, rarely possessed by a youth of twenty years of age; and it unfortunately happens, that a season rarely elapses without one or more of our most hardworking young men falling a sacrifice to their close application. I would, then, take this occasion of submitting to the Examiners for the Apothecaries' diploma, the expediency of extending some of their prescribed courses of lectures into the summer season,—an arrangement that would much lighten the winter season, and virtually lengthen the period of study, by compelling young men to remain in town during a part of the summer, instead of passing that season in other than intellectual pursuits. For example, the lectures on *Materia Medica*, on *Medical Jurisprudence*, and on *Botany*, might, (if it met with the concurrence of the respective lecturers on these subjects,) with advantage both to pupil and to teacher, be deferred to the three summer months of June, July, and August. Such an arrangement

would permit the pupils to pass a month (May) in the country, at the conclusion of the winter season, and a second month (September) at the termination of the summer course. I say, with the concurrence of the lecturers; for, in making regulations of this nature, it would savour a little of courtesy, if the Court of Examiners would consult the lecturers before passing regulations, by which the latter are principally affected. The medical chairs in the schools of this metropolis are, with few exceptions, held by physicians, who are entitled at least to a little courtesy, if not to deference, as to the line of study that is chalked out for their pupils; and although, by the accidental operation of the law, the Examiners of the Apothecaries' Company are enabled to issue laws establishing professorships, and dictating the order of attendance upon lectures, yet, an appeal to the opinion of men, who have received a somewhat more extensive education, and therefore are, at least, equally qualified to direct their pupils' course of study, might enable them to arrive at a more correct conclusion, as to what is fitting and

expedient in conducting medical education.

I would also take the liberty of suggesting to the Court of Examiners, and I do so with a pretty extensive experience of medical pupils, that the character of the medical student is much improved within the last ten years; and, that the order in which the lectures on *Materia Medica* and *Medicine* should be attended, might, with safety, be left to the discretion of the students themselves. Regulations that are not absolutely necessary, only encumber the student, and hamper him in the distribution of the limited time he has to bestow on his multifarious pursuits. Few arrive in town, especially since the establishment of provincial schools, without some knowledge of chemistry, botany, and *materia medica*, and a considerable share of practical experience in medicine; and, I venture to affirm, that, if left to themselves, as to the order of attending lectures, they would be able to parcel out their time to more advantage, and obtain upon the whole more extensive acquaintance with the different subjects, than any compulsory clauses or quarantine laws of education can enable them to acquire.

After perusing the above routine of medical and surgical education, as now conducted at our principal metropolitan hospitals, it needs but little argument to convince the student of the utter impossibility of effectively bestowing his attention on all these important branches of his education, unless he is able to lighten his labour, by having previously obtained an extensive acquaintance with anatomy, before he commences his studies in town. Provincial schools afford him, during his pupillage, the means of gaining this solid foundation: it matters not on how limited a scale their operations may be conducted; ability and zeal on the part of the lecturers, and industry on the part of the student, will stand in the place of a more extensive field of operations.

The objections so frequently urged against the long period of apprenticeship, as required by the existing laws, vanish, when the instruction received by occasional attendance on lectures during apprenticeship is taken into consideration. The mind of a surgeon's pupil, who possesses these advantages, becomes early drilled and ini-

tiated, not only, as heretofore, in the mechanical art of dispensing medicines, but in the interesting walks of science. He is insensibly led to form a just estimate of the profession in which he is embarked, and to take early delight in those pursuits which are to form his principal study. At the termination of his apprenticeship, with mind well prepared by previous habits of study, and a disposition to take advantage of every opportunity that offers of obtaining information, he comes to a large hospital, where he soon begins to find the value of his previously acquired knowledge. Instead of being obliged to devote his time to the acquisition of the elementary principles of science, he is able to see and understand their application in practice; instead of exclusively passing his valuable time in the ordinary occupation of a dissecting-room, which the pupil uninformed in anatomy is compelled to do, he can select his subjects for dissection, and more accurately inform himself in those parts that are concerned in operations and practical surgery. He is able to spare more time for observation of disease at the bedside, aided by the remarks of the physician and surgeon; his previous information divests his pursuits of that irksomeness that must attend a course of study directed solely with a view to pass an examination; and he feels and regards his studies rather in the light of a pleasant pursuit, than as an arduous and laborious task.

It were endless to attempt to enumerate or to describe the advantages and influence of previous study on a young man, before he comes to a large scene of disease for the completion of his education. But there is one, in which is comprised so much that is good, that it deserves to be especially pointed out—I mean the utter extinction of that pernicious system, technically termed, "grinding": the demands made on a student's time have hitherto rendered this process to a certain extent unavoidable; a young man must have a retentive memory, indeed, who can pursue science as it ought to be followed, and at the same time retain in his mind, at the end of two years, those points which an examination calls for. The student, who conducts his studies solely intent upon his examination, will charge his memory with the details of his subjects,

to be forgotten as soon as they cease to be subservient to the purpose for which they were acquired.

Strongly impressed with the necessity of medical pupils of the present day coming to town with some knowledge of the subjects of their future studies, I have thought it right to impress on their minds the immense advantages which the schools in large towns hold out to them, assuring them that they will sensibly feel the benefits arising from them during the whole of their professional career. Those who pass their apprenticeships in towns too small for the existence of a regular school, I would recommend to form associations, with the assistance of one or two well-informed surgeons, for the purposes of regular instruction.

With apologies for the length of this letter, I have the honour to remain, sir,

Your obedient servant,

C. ASTON KEY.

St. Helen's-Place,
Nov. 20, 1831.

HOSPITAL PUPILS.

To the Editor of the London Medical Gazette.

SIR,

I TRUST you will pardon my addressing you on a subject of deep importance to the pupils who are attending the surgical practice of the united hospitals of Guy and St. Thomas. I have, sir, to complain of the liberality (I *must* be allowed to say ill-judged) of the officers who are connected with those useful institutions, which are so deservedly renowned for the great advantages, and the wide and extensive field of observation, which their well-filled wards present to the diligent and industrious student. The persons (very many of whom are not pupils) who accompany the surgeons round the wards, are so numerous that it is impossible for more than one patient in three to be seen; and consequently much interesting clinical instruction is lost, by many of those who are actually pupils, from the distance at which they are necessarily placed from the surgeon and the patient. If those who have not entered to the hospital at all, or who do not even attend a course of lectures there, be allowed to see the practice at the expense

of the exclusion of those who *have* paid for admission, of course there can be no possible advantage in paying the admission fee of 26*l.* 6*s.* This, sir, certainly ought not to be, and I feel assured that Messrs. Key, Morgan, and Cooper, whose kindness, attention, and anxiety to afford instruction to their pupils, are so generally acknowledged, will use every means in their power to correct the important abuse, if it were sufficiently made known to them, and I earnestly trust some means will be taken immediately for the exclusion of those who have no right to intrude themselves into the wards, to the great disadvantage of those gentlemen who have paid for their admission.

If, sir, the all-absorbing and important subject of cholera, upon which you are now so philanthropically engaged, will allow you to find space for the insertion of these humble observations, you will confer an obligation on

Your obedient servant,

And constant reader,

A PUPIL.

Borough, Nov. 15, 1831.

ANALYSES & NOTICES OF BOOKS.

L'Auteur se tne à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Observations on the Nature and Treatment of the Cholera Morbus, now prevailing epidemically in St. Petersburg. By GEORGE WM. LEFEBVRE, M.D. Member of the Royal College of Physicians of London, of the Royal Medical Society of Edinburgh, and Physician to the British Embassy, St. Petersburg. 8vo. pp. 96.

THERE is a pleasant sketchiness about Dr. Lefevre's manner of treating his subject, which is well calculated to win the reader's attention; and we take leave to think, that this is no small recommendation for the work before us, now that the public are beginning to tire of controversy about the nature and causes of cholera, and to look for something practical and decided as to its history and treatment, be the same of what authority it may. Steady, sober

narrative, and logical argument, even upon this all-important subject, are, we perceive, growing wearisome and unfashionable—at least, if we may judge from various remarks appearing daily in the non-medical publications, betraying but too often a bitter spirit of ill nature towards the members of our profession, simply because we cannot supply the sapient grumblers with understanding enough to sift what they read—to recollect that they peruse hastily the opinions of individuals—and that there is no one possible topic of controversy, upon which there will not be almost as many different opinions as there are thinking individuals employed to think about it. Dr. Lefevre's book, however, may be read by these non-contents as a diversion—not that they will find it a whit more decisive in its tenets about the theory of cholera, or more practical in its precepts, than many works which have already appeared; but there is a lightness in its whole construction which renders it rather refreshing in the perusal. The doctor is a non-contagionist; we are sorry for it; though, we fancy, he is so far from being decidedly so, as that were he among us just now we could easily persuade him to confess himself “a *contingent* contagionist” at least, which is the most newly-adopted and saving title of the party with which he seems rather inclined to identify himself. At all events, Dr. Lefevre, who finished his book at St. Petersburg in September last, acknowledges himself a non-contagionist merely for want of *more facts*; and that is as fair a reason as we can expect any man in similar circumstances to give. We wish all those who profess to belong to the same creed of scepticism, were equally candid in their acknowledgments.

Dr. Lefevre derives his experience of cholera from his personal attendance on “a large though not very populous district” of the Russian capital, during the prevalence of the late epidemic; and the “Observations” now before us are the substance of the reports which he then and there made to the chief inspector of his district. “In fulfilling this task (says Dr. L.) I was induced to enter more at large into the subject, and as I imagine that the observations of an individual, or rather a comparison between the observations of different individuals during the late malady, cannot be wholly without

interest, I have been induced to send the following to England for publication.”

The author's account of the manner in which cholera invades a country, or a town, is curious.

“Among the most striking features in the propagation of this disorder, is what may be styled *its eccentric motion*;—and, true to its eastern character, it presented this feature here, not only in its passage through the country, but even in its dissemination over the different parts of a town which it invaded. In its progress from Tiflis to Moscow, it was *observed to move in a zig-zag direction*, rather than in a regular line of march. It would pass by a town which lay immediately in its path, to appear in another, which it must have reached by a very circuitous route. When it invaded a town, it followed the same law; touching at a point to *fly off at a tangent*, and appear at a widely separated part from that where it first commenced, leaving the *intermediate spaces uncontaminated*.”

This is, to be sure, not a little fanciful; the doctor thinks himself a non-contagionist, yet, according to the preceding *eccentric* account, the disease is progressive, *moving*—that is, as we conceive, attacking individuals—in a *zig-zag direction, flying off at a tangent*; which, if we can understand our author, means that new seizures are observed along a line of route situated laterally to its recent line of progress; whilst it appears that it is only somewhere at the extremity of the tangent that new cases occur, the *intermediate spaces* (that is, of course, the tangential line) being left *uncontaminated*. Now, pray, how does Dr. Lefevre know that the disease follows the direction of a tangent, if it only appears at the two extremities of the supposed line, and never manifests itself between them? Perhaps it jumps, or takes flight like a bee; or, more soberly, what is to prevent us from supposing that it is carried in a coach, or goes in the company of some traveller? Dr. Lefevre thinks, however, that there is something in it much more mysterious than this; and if ever he hears of its passing by a town in the course of its progress, and appearing beyond it, takes it to be a voluntary act on the part of the cholera, or only attributable to its eccentric propensities—not seeming to care for in-

quiring whether it has been excluded unceremoniously from the said town or not.

“ ‘The disease,’ says Dr. Kennedy, ‘would sometimes take a complete circle round a village, and leaving it untouched pass on, as if it were about wholly to depart from the district. Then, after a lapse of weeks, or even months, it would suddenly return, and, scarcely reappearing in the parts which had already undergone its ravages, would nearly depopulate the spot which had so lately congratulated itself upon its escape.’ ”

“ ‘This whole passage (says Dr. Lefevre) is applicable to St. Petersburg at the present moment; for though last autumn we were surrounded on all sides by the cholera, still we escaped during the winter and succeeding spring. Seven months had elapsed since its appearance in places not far distant from the capital, and we began to think that the imperial city would escape its ravages.’ ”

“ ‘There is a striking resemblance,’ observes Dr. Kennedy, ‘between the propagation of the plague, as described by Procopius, and that of cholera. It always spread from the sea-coast to the inland country; the places which had escaped the fury of its first passage, were alone exposed to the contagion the second year.’ ”

“ ‘People (at St. Petersburg) resumed their usual avocations and their ordinary diet; they began to regret the privations they had voluntarily undergone in abstaining from various articles of food which they considered dangerous. The profusion of fruit which pours into Petersburg from all the southern provinces, but particularly the grapes and water-melons from Astracan, had, the preceding season, been allowed to rot in the hampers in which they were imported. The supposed preservative means were now generally laid aside, and the houses were no longer redolent with the fumes of chlore, tar, and juniper, which poisoned the antechambers. The family receipt-book was no longer conned over by day and meditated upon by night, and Buchan and Thomas had already been replaced by Fairy Tales and Travels in the East. The medicine chests and prescriptions of each confidential physician were altogether discarded; castor-oil and opium fell again to a moderate price;

and, indeed, the confidence in the faculty was much shaken, when it was ascertained that the means employed by the common people were equally successful with those adopted by the profession itself. Some few, however, continued to use the same precautions as heretofore, and even took medicine by anticipation. Some even fell victims to such an absurdity. In the midst, however, of this almost general oblivion of the past, the *hydra-headed monster* was upon his route; for the evil day had only been postponed.”

And with what deadly effect the “hydra-headed monster” came at last into the Imperial city—and what a panic he created there by his actual presence—are too generally known to need a repetition from us. We have thought it right to give the preceding passage, however, as one pregnant with a moral not inapplicable to present circumstances among ourselves.

In his account of the symptoms of cholera, Dr. Lefevre is not so alarming as certain other writers: we give a specimen. Speaking of the great majority of ordinary cases, he says:—

“ ‘The affection of the head was almost universal, but it was of different kinds. Sometimes the patient complained of a sudden lancinating pain, which was of momentary duration; at other times the feeling that is produced by fainting, dizziness before the eyes, dimness of vision, *muscæ volitantes*, preceded the attack.’ ”

“ ‘The following case illustrates a peculiar feeling in the head immediately preceding an attack of cholera. The person was seized in my presence, whilst giving directions regarding the arrangements of a large hospital, over which he presided. He was sixty years of age, and apparently in perfect health: whilst in the midst of conversation he suddenly put his hand to his head, and complained of a sharp pain passing through the temples, which lasted but for a few seconds; he ascribed it immediately to having taken a pinch of snuff from a neighbour’s box, which being stronger than that which he habitually took, it had got into his head. The sensation passed off, and he resumed his conversation. This took place at nine o’clock, P.M.; at eleven he was seized with other symptoms of cholera, and died of the disease after five days’ illness.’ ”

“ ‘Though I have almost universally

found an attack of cholera preceded by something bordering upon vertigo, yet, in one rapidly fatal case, no such feeling was present till it was produced by the weakness caused by the evacuations."

The vomiting in cholera, Dr. Lefevre describes as very similar to what is seen in sea-sickness: while lying in a horizontal position, the patients do not experience much nausea or desire to vomit; but upon raising their heads, they commence vomiting immediately, and with that kind of straining which we witness in sea-sickness.

In his account of treatment, our author is very copious: he divides the subject into the external and internal treatment; and under each head examines the various classes of remedies which are commonly employed. Some of the remarks in this portion of the volume are extremely well worthy of perusal.

A maplike table, indicating the progress of the cholera at St. Petersburg, is prefixed to the observations: it is an ingenious mode of exhibiting the numbers on the sick-list at each successive date; but for want of a little explanation, we have seen some readers sadly puzzled to make out what it meant.

Cholera, its Nature, Cause, Treatment, and Prevention, clearly and concisely explained: with an Appendix, containing practical Remarks on Fever and Dysentery, with which Cholera is intimately connected and frequently combined; being the Substance of Reports made to the late Government of Poland. By CHARLES SEARLE, Esq. of the Hon. East India Company's Madras Establishment, and lately in charge of the principal Cholera Hospital at Warsaw. Second Edition, revised and enlarged.

THIS little brochure is a second and enlarged edition of the one we recently noticed: it contains some useful hints, and has the advantage over many others, of giving the results of actual experience and observation at the bed-side of the sick. Its chief fault is a want of arrangement and a defective perspicuity. There is nothing absolutely new in Mr. Searle's present recommendations: an emetic of salt in warm water; small bleedings, local or general; calomel almost always, and purgatives occasionally; heat, rubefacients, and

frictions externally;—such are the chief means of cure suggested. Mr. Searle is a non-contagionist, but he must forgive us for saying, that, looking only on what was within the range of his own vision, and magnifying its importance like what is seen through a microscope, he loses sight of the general bearings of the question as a whole. The pamphlet, however, with all its defects, has more claim to attention than many of the productions on the same subject, under which the press at present groans: the quantity of catch-penny trash constantly handed to us is amazing.

—

Reports of Medical Cases. By DR. BRIGHT. Price 9l. 9s.

[Continued from page 201.]

—

Apoplexy of the Spinal Cord.

HAVING concluded his remarks on pressure of the brain occasioned by sanguineous effusion, and on apoplexy generally, Dr. Bright presents us with an excellent case of apoplexy of the spinal cord, for which he acknowledges himself indebted to Dr. W. Stroud. The following abstract is taken from Mr. Stroud's own words:—

Mr. Benjamin B., aged 48, was engaged during the greater part of his life in the merchant service at sea, performed many voyages to India and China, and in general enjoyed good health. In 1812 he received a violent chill at St. Helena, which brought on a rheumatism, with which he laboured for many years. The muscles of the trunk both before and behind were occasionally affected; his bowels were habitually costive, and the digestive organs generally out of order. This was his last voyage. He engaged in commercial business at home, but, not proving successful, his health suffered through care and anxiety; he fell into a declining state, attended with nervousness, increased flow of urine, and some degree of emaciation. On the night of April 20, 1826, he sustained a slight paralytic attack, by which his mind and speech were a little disordered, and all the muscles on the left side were weakened. From the effects of this attack he never recovered; neither his articulation, however, nor his faculties were sensibly impaired; and, from being at first hemiplegic, he gradually became paraplegic,

in which state he died April 16, 1827. During the two months preceding his death, the palsy having decidedly seized the trunk, the use of the catheter became necessary. There was also sloughing about the nates, of the fetor from which his olfactory nerves were sufficiently acute to render him conscious. The act of death may be said to have occupied thirty-six hours; the powers of evacuation, speech, deglutition, the mental faculties, and the remaining muscular force, were successively extinguished. The respiratory function ceased the last. "As he sat up in the bed supported by pillows, the head and body vacillated from side to side; the breathing became laborious, and sometimes moaning and stertorous; the eyes were half-closed, and had a wild and vacant expression; but as long as the power of communication continued, he signified that he was free from pain and distress."

Upon examining the head and spine, the following appearances were observed. The brain was sound, with the exception of a little serous fluid between the membranes, and some congestion in the veins of the pia mater. The disease had been apparently seated in the coverings of the spinal cord, which exhibited evident marks of inflammatory action, although the cord itself presented no visible derangement. Serous fluid, in considerable quantity, was found between its membranes, and the arteries of the pia mater were much injected. "Within the upper dorsal vertebræ, on the left side, rather more than an inch in length, in the direction of the spinal axis, and about half an inch in a transverse direction, was an apoplectic cell, containing the red and broken remains of a coagulum; and lower down in the spinal canal, the internal ligament was to some extent deeply marked by ecchymosis, as if in progress towards the formation of another similar effusion. The extravasation appeared to have been wholly external to the cord, which was in consequence compressed; but, as far as could be perceived, it was neither disorganized nor inflamed. The coagulum seemed to be subjacent to the pia mater, and to be enclosed in a false or adventitious membrane."

Here, then, was clearly hemiplegia of the left side, arising from an apoplectic effusion on the same side of the spinal cord; although the right side of the

brain, it should be observed, did certainly exhibit an undue degree of vascularity. This, however, agreed perfectly with the symptoms, and more especially with the fact that the complaint was purely paralytic, and eventually assumed the form of paraplegia, while the senses and the mental faculties were not obviously impaired.

It is justly observed, by Dr. Stroud, that we may derive several useful and interesting conclusions from the history of the foregoing case. For example, it would appear that conditions purely nervous, and originating in long-continued mental disturbance, may, according to predisposition, induce an inflammatory or hemorrhagic state of the membranes investing the brain, or the spinal cord; and that this state, operating through the medium of the nerves, may exert an extensive influence both on the solids and on the fluids of the body. Under the exacerbations which repeatedly occurred in this case, the intensity of the secondary irritation progressively advanced, from itching and smarting to severe rheumatic pain, chiefly between the shoulders and on the affected side. The blood became buffy; the bile dark-coloured and concentrated; the alimentary canal abounded with acidity. Without any apparent disorder of the stomach and bowels, the tongue used to become red, or foul, or parched; and all this obviously from the state of the nervous system. The excitement which proceeded from the left side of the spinal cord to the right side of the brain, furnishes an interesting illustration of an occurrence which usually takes place in the opposite order of succession, and affords additional evidence that the corresponding halves of the central mass of the nervous system decussate in the medulla oblongata.

PRESSURE OF THE BRAIN resumed.

Pressure from Tumors.—The first case with which our author illustrates this morbid condition of the brain, is so very curious and interesting that we are sure our readers will be in no small degree obliged to us for giving them a pretty copious abstract of it. It is a case in which a large tumor was found attached to the dura mater, and descending deeply into the anterior lobe of the cerebrum.

A. Z., a gentleman of about fifty

years of age, had been for a considerable period subject to severe attacks of headache, which always began at the forehead. He had had a small encysted tumor removed from that part fifteen years previously, but never had any suspicion of the possibility of a connexion between his unpleasant symptoms and the almost forgotten tumor, until questioned strictly, during his illness, with respect to past occurrences serving to throw light on his perplexing case. He was subject to gout also; which, however, only seemed to render him more attentive to his diet. But all this never created any uneasiness among his friends: it was not till the summer of 1824 that they began to be seriously sensible that all was not right, from the circumstance of his newly-acquired listlessness and indolence, so much at variance with his former habits.

"In January 1825," says Dr. Bright, "I first saw this gentleman as a patient; at that time the long continuance of his bodily weakness, and his mental failure, and their gradual increase, had begun to inspire his medical attendants with a fear that chronic organic disease might be taking place: he was perfectly collected, and able to answer questions, but he was unwilling to do so; would sit on the sofa and read the newspaper without paying any attention to it; said that he felt occasionally, as he sat, a tendency to be drawn to the left side, or rather to give way on that side: he could walk across the room quite alone, but sometimes could not direct his steps, and sometimes rather ran than walked; he could still play at cards with his family for amusement in the evenings. Occasionally he had headache, and now and then became very drowsy for a day or two together, pointing, when asked, to his forehead as the seat of pain. At this period he would sometimes become very irritable, and almost irrational on some points—more particularly, he would often call for his great-coat and insist on going to the theatre, and it was scarcely possible to prevent his going. It was obvious that from month to month he became more infirm, although at times the drowsy fits passing away, or other casual ailments subsiding, seemed to give hope that a favourable change was taking place. It was remarked that he became more and more helpless, and more absent every day; for many months before, he had some-

times been so absent as to stop in the street looking at indifferent objects for a long time together, and by this means probably arrive an hour after the appointed time at a dinner-party; at other times he would sit after dinner, taking his wine with one or two familiar friends, without speaking a word, which was quite contrary to his usual habits. He would now sit for hours together totally unoccupied, and without saying a word; and he not only rose very late, but would frequently spend two or three hours in dressing."

In the course of the summer, he had to be wheeled about in a chair; the sphincter of the bladder lost its power, and his drowsiness increased to an alarming extent. A blister to the scalp produced erysipelas of the face, stranguary, and a violent spasmodic shaking of the left hand. Some months after this, a helplessness and a lethargic condition came upon him, that rendered him a mere infant; though he was certainly conscious of those around, and very thankful for the care taken of him. He was frequently incoherent in his ideas, fancying that he had seen certain persons of distinction, and public characters, who had never been near the place, and constantly saying that he was going out to dine with some one. Strabismus was now observable, and slight distortion of the features; deglutition difficult—sometimes alarmingly so. The tongue, which for years had generally been foul, and often had a thick stripe of dark fur towards the base, became loaded in a most extraordinary manner with a thick olive-coloured coating. The sphincters now lost their power irrecoverably. The left hand and leg seemed partially paralysed. The action of the skin was changed: profuse perspirations would occur for weeks together. Every feasible plan of treatment was tried, but to no effect. A severe epileptic fit carried off the sufferer at length, in July 1826. The following we think well worthy of being extracted.

"*Sectio Cadaveris.*—On removing the skull, the vessels of the dura mater were rather turgid; and raising the membrane it was found to adhere to the parts below on the anterior portion of the right hemisphere of the cerebrum, more particularly about an inch from the front near the longitudinal sinus, where the adhesion was perfect, with an appearance of vessels radiating over the hemisphere. The surface of what appeared to be brain at that part was obviously changed,

and lobulated in its structure; and it would appear that the great aggravation of symptoms leading to the fatal termination, was connected with a softening and a watery infiltration of the brain in the neighbourhood of the tumor.

Two cases are next given of tumors formed by disorganization of the brain, causing hemiplegia: both terminated fatally. We have then an interesting account of a case in which there was stupor and other symptoms of pressure without paralysis; but in which, after death, there were found two or three hard tumors in the anterior lobe of the cerebrum. After this comes a case of scrofulous tubercles in the brain, producing paralysis and great irritation: some of the particulars we must extract.

Amelia Humphreys, aged eleven, was admitted under Dr. Bright's care in November 1829. Five months previously, up to which period she had been a healthy child, though delicate, she had a fit at school, and never completely recovered after. By leeching and blistering she was enabled, in about a month after the fit, to feed herself and walk with but little assistance. She relapsed, however; and upon admission at Guy's presented the following symptoms:—The left leg incapable of motion—stiff, cold, shrunk, and firmly extended; the foot drawn inwards. The right leg almost similarly affected; but both legs are sensible to the touch. The use of the upper extremities impaired; the back stiff and rigid; the feces and urine pass involuntarily; she screams occasionally, and complains of her head. Ordered to have her head shaved, and the common embrocation applied. *Habeat Pil. Galban. comp. et Pil. Aloes c. Myrrha aa. gr. v. omni nocte.*

A seton was applied to the nape next day, and her bowels being relaxed she was ordered *Hydrar. c. Creta, gr. ij. bis die, et Inf. Cascariæ cum Soda, ter die.* Beef-tea, Arrow-root, &c. &c. The appetite good.

" 11th.—Abdomen greatly swollen last night; the breathing shorter and more laborious, effected chiefly by the diaphragm. Hiccup came on early in the morning, and has since subsided; the respiration and pulse were then exceedingly rapid; they are this morning 40 and 160 respectively: the irritable habit and fretfulness have subsided,

209.—IX.

and there has supervened a state of oppression without coma or delirium; indeed she is remarkably distinct in her answers, recollecting circumstances regarding her health which occurred long ago; the appetite, which was great, is almost gone; the countenance pale, but the cheeks are suffused from time to time with a purple flush; the abdomen is rather tumid, the feces always passed involuntarily; the right arm is bent over the body, and firmly contracted, stiff, and inflexible; the spastic action of the muscular fibre may be felt by laying hold of the right arm or the left leg; the eyes are directed to the left, and she does not move them when requested, or when spoken to: there was observed, after taking nourishment this day, a violent spasmodic action of the muscles of the left side of the face, particularly the mouth.

" Nine o'clock, P.M.—Comatose and insensible; the eye-balls, which before were fixed, are now constantly rolling; the mouth is drawn to the left side, not permanently, but spasmodically; the mouth is nearly closed, and frothy saliva rests upon it. Pulse 176, not faulting; the extremities and head warm; hiccup renewed occasionally; abdomen tumid; the muscles of the extremities are constantly quivering and twitching; she has taken nothing since five o'clock.

" 12th.—Dissolution seems to be approaching; the breathing sonorous, with mucous tracheal rattle; a miliary eruption, forming small transparent vesicles, has appeared over the whole chest; eyes dim and fixed; pupils contracted; pulse flags during inspiration, and then beats three or four hurried strokes during expiration; forehead and extremities very warm. Expired at half-past four o'clock.

MEDICAL GAZETTE.

Saturday, December 3, 1831.

" Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."—CICERO.

AN APOLOGY FOR HUMAN DISSECTION.

THERE are three questions which seem to us to comprehend the whole matter

Y

at issue between the profession and the public with regard to the application of the dead to the use of the living. They are questions to which all those delicate interrogatories may be reduced which for the last two or three years have been asked us, and which we never remember to have heard urged with more interest or earnestness than they now are, in almost every company that we happen to frequent. 1. Is it possible that a sufficient supply of bodies cannot be obtained for the schools without a temptation being held out to wretches to commit the crimes of exhumation and murder? 2. Cannot medical men do without dead bodies, and be content with artificial contrivances in their stead? And, 3. Would it not be better to be without these cruel cold-blooded surgeons altogether than countenance them in the profanations which they commit? This last question, however, we take leave to get rid of summarily, before we go farther: we never reason seriously with any one who proposes it, for we generally find such person to be a wag, a fanatic, or a fool: at all events, we have always found it most convenient to direct such people to the miracle-mongers of Regent-Square, or the humane practitioner in Harley-Street. We therefore conceive ourselves as having to deal with but two sets of inquirers—persons not unwilling to take for granted that there will always exist a necessity for physicians and surgeons in the world, and that if these said surgeons and physicians may not be permitted to learn their profession, so much the worse for their patients—quacks will abound, and manslaughterers must be winked at. Our postulate is simple, but not superfluous; and we can safely recommend it, from experience, as the best possible *shibboleth* by which reasoners on this subject may test the value of their opponents.

Now with regard to the first question—which comes, we presume, from those who think burking and unburying su-

pererogatory iniquities wantonly and unnecessarily perpetrated by monsters who are blots upon humanity—we admit the full force of their impressions of the crimes and criminals engendered by the present modes of supplying the schools; but unfortunately, constituted as society in this country is—such, we mean, is the state of the laws by which we are governed—the wants of the profession, or of the community rather, afford no slender apology for the existence of such crimes and criminals amongst us. In plain words, we reply, it is impossible that in the present state of things the schools can have any thing like a sufficient supply of subjects without exhumation and murder: nay, what is worse, even *with* the aid of these atrocious enormities, the supply is exceedingly scanty, and must every day become more and more so, by reason of the increased vigilance of the authorities employed in the suppression of crime. But in desperate emergencies, proportionate efforts of desperation will always be made; nor will miscreants be found wanting as long as their services are required. And surely the time is now come, when, if ever, the danger of ministering to the wants of anatomical science is at the highest. Never was the risk of life more obviously to be incurred, or the temptation to risk it more alluring; yet have we no hesitation in saying, that unless the strong hand of power be exerted to put down the schools altogether, they will still be supplied (however scantily); nor will desperadoes be deficient to attempt that supply, at whatever hazard.

It was thought at one time that nothing could go beyond the following picture of iniquity. Two officers of police are examined before the Anatomical Committee:—

“ You pretty well know who the men are in London who pursue this trade [that of body-snatching]?”

“ Yes, we cannot help knowing

them : we are out all hours, and *running against them*. * * * I have recovered between 50 and 100 bodies for persons whose houses have been broken open, and the body stolen out of the coffin prior to their being buried."

"Do you think many bodies are obtained by breaking into houses and stealing the bodies previous to burying them?"

"There have been *a great many*. * * * I have known many cases in which the different parties of resurrection-men have quarrelled, and have broken into one another's houses and stolen the bodies before they could be conveyed to the theatres ; and they have been so violent that they have *cut a body into pieces*, and carried it to the opposite party's house, and raised a mob there."

"Have you heard, that to destroy the work of another, they go to the churchyard, and leave the coffins standing upright?"

"Yes, I have known them *fight in the graves*."

"Then you probably think the resurrection-men, with some few exceptions, the most worthless class in the community?"

"*The most dreadful*."

Yet these were only a sample of the resurrection-men who flourished before the iron age of Burke and his successors was revealed ; these were never once suspected to be capable of the *coup de grace* which promises to render the present æra infamous in the annals of crime. But enough of this odious topic, on which we fear we have digressed unreasonably : to return, then, our answer to the first question is briefly this—there is *no* possibility of getting any supply for the anatomical schools without an infringement of the law, by exhumation at least ; and with this, under the most favourable circumstances, the supply is but scanty. The inference, of course, is, either that some effective expedient must be adopted by the legislature, and sanctioned by general consent, whereby the schools may proceed in their honourable pursuit uninterruptedly, or, exhumation must at

least be connived at, and the present precarious supply continued. The latter alternative, we need scarcely remind the reader, perpetuates and encourages the dangerous order of miscreants whose deeds are beginning to cry aloud for vengeance.

It is full time now to come to the second question—and an important one it is, as it forms the strong hold and refuge of most of the puny babblers in society. They have learnt how to shift it about, and to present it in a variety of shapes. It is a broad question of substitutive expedients, which, one by one, demand a sufficient answer : there may be fifty of them, with an *et cetera* at the end, and the challengers may fly from one to another with consummate skill and untiring pertinacity. But we shall try to draw a moderate circle round them, and reduce them to a limited number of their ingenious devices. "Why," says one, "will not the teachers of anatomy and surgery avail themselves of the elaborate and learned works of their predecessors ? there they will find ample plates and eloquent descriptions ; surely these should suffice, without mangling and hacking up the recent subject?" "Why," says another, "will not the dissection of animals, of cats, dogs, sheep, monkeys, &c. answer every purpose, without inflicting indignities on the human dead body?" "Why not employ wax models?" says a third : "nature can with these be imitated in the nicest point, and they are beautiful to look upon." "Why," says a fourth, "are not drawings multiplied in profusion, and made to represent every possible part of the human frame?" And, lastly, "is there no machinery whereby the human body may be so represented in wood, leather, cloth, silk, and so forth, as that operations may be learnt upon it without practising on the actual flesh?" These, we believe, are the principal subordinate

queries into which the proposers of the second question usually resolve it. To each of them separately we shall offer a brief remark or two; but first we shall take the liberty of suggesting that they are all confessedly intended to point out mere substitutes for a genuine commodity. We could, if we were at all inclined unceremoniously to cut short the argument, readily do so by one plain practical question. In the event of some serious accident, or acute bodily suffering, befalling one of our nearest connexions, and that we conceived life or death to depend on the choice we made of the practitioner whom we should call in, would we hesitate a moment, *ceteris paribus*, between him who had laid the foundation of his professional knowledge by the practice of human anatomy, and him who had obtained never so high a character by his operations on machinery, and his contemplations of lithographs and wax-works? But we will not press for a reply; but rather, for argument sake, say something distinctively on the make-shifts.

With respect to the "elaborate and learned" works of the elder anatomists—with all due regard for those eminent authorities—we submit that there has been no art so slowly progressive—none in which the principles and facts have been laid down with more uncertainty by the early writers—whether owing to the precarious opportunities of observation which they enjoyed, the rage for paradox and discovery which sometimes possessed them, or the imperfection of the arts of engraving and wood-cutting at the times in which they wrote; added to which we may mention, that even if they were at all valuable as substitutes for the thing itself which they profess to describe, and not so full of mistakes as they really are, they still are very costly, scarce, and inaccessible. No books are more obsolete than old ones on descriptive anatomy—no books more

curious for their fanciful but dangerous errors. Every modern lecturer and demonstrator on the human body is well aware of this, and finds it his duty to expose the fact to his pupils—to guard them against the speculations of the old observers.

It is to the modern systems of anatomy that the student must have recourse for guidance and assistance in his labours: they will serve to direct his pursuits, but that is all: they can no more make him a practical anatomist or surgeon than reading all the books that were ever written on chemistry could make a dextrous experimentalist of one acquainted with apparatus only in engravings and wood-cuts.

The proposal to substitute comparative for human anatomy, is absurd upon the very face of it. It is true that the dissection of animals can throw much light upon the structure and functions of the human body; but only collaterally and by comparison, as the very name given to the study implies. It was by a fatal, though perhaps unavoidable proceeding of this sort, that many glaring errors have been set down in the works of the fathers of physic. We should like to know how the matter would be mended if the rising generation of anatomists were to be put off with a supply of monkeys for men—though the substitution of "monkey" for "human shambles," might serve, perhaps, to stop old Cobbett's mouth. What a spectacle for Europe and America, to behold cargoes of monkeys from the Brazils and from Africa, to be killed and dissected for the education of British anatomists! Why it would be a sort of murderous slave-trade revived.

Then, as for wax-works, they are certainly, as we have seen them in some modern specimens, "very beautiful to the eye," and, being truly modelled after nature, very useful as a help to the memory of those who have already dis-

sected: but the pieces must be innumerable, if we wish with them to supply the place of any required dissection; and for this the expense must be most enormous. For colleges, and the museums of wealthy individuals, a set of wax models must be a most desirable collection; but it is ridiculous, in point of genuine utility, to compare them with dissections of the recent subject, executed with the student's own hand.

The same objections which belong to wax-works apply also to drawings or engravings—which *must* be multiplied, and therefore become intolerably expensive to the great majority of medical students. And, by the way, we have never heard how surgical operations are to be taught on either drawings or wax models.

But these, forsooth, may be taught on machinery: an artificial *man* of some sort is to be constructed, and the operations thus to be demonstrated. Preposterous! Why, surely, these people must think that Frankenstein is no fable, and that Prometheus really stole fire from heaven. Nothing comes amiss to their credulous maw. We really feel more than half inclined to send these notable speculators to the same limbo of vanity to which we adjudged the propounders of the third question.

And now that we have fairly met every objection, bearing upon its front the show of reason, against that side of the argument which we have adopted, we think we may venture to close this part of our remarks. Our object was popularly to point out the folly and ignorance of those who raise a cry against dissection, on the supposed ground of its being not indispensable—as if medical men took up the knife “to mangle the dead,” out of some inhuman propensity to commit a wanton outrage. We have shown, we hope satisfactorily, that none of the *humane* expedients proposed by the opposers of

dissection, have the least value in comparison with the actual human dissection itself—and that, therefore, the latter being indispensable, unless medical science be to be thrown back into primitive barbarism, we are bound to forward its interests as far as in our power lies. In our next, we hope to have an opportunity of stating more particularly what we think the friends of anatomy ought to do. It so happens that certain recent occurrences, however shocking to humanity, seem favourable to the prospects of the medical art: and, if they are, they must be almost as directly subservient to the well being of the community at large. None, we are sure, but the most “obstinate malignant,” will presume to impute selfishness to the stir we now make; but, however that may be, no influence of so sinister a description shall ever have the least weight with us in deterring us from our purpose.

—

REMEDIES TRIED AT SUNDERLAND IN CHOLERA — OTHERS SUGGESTED.

WE mentioned last week that a hog's-head of brandy, already mixed with laudanum, in due proportion, had been furnished by government for the use of the cholera patients at Sunderland. We regret to say, that little benefit has been derived as yet from this, the volatile oils, or any other method of treatment which has been tried; nor has any thing occurred to throw any additional light either on the nature or treatment of the disease. The inhalation of oxygen has been tried in several cases without any apparent advantage; the pulse, indeed, rose a little during the inhalation of the gas, but immediately on leaving it off, the sinking of the pulse was found to be greater than before its use. Some nitrous oxide was in preparation a few days ago, and ere this, we doubt

not, has been tried. We must confess, however, that we entertain little hope from this class of remedies, because the lungs do not act upon that portion of oxygen which the air naturally contains, it having been long ago ascertained by Dr. John Davy in India that only from one-fourth to one-third of the proper quantity of carbonic acid was found in the air expired by those labouring under cholera. A galvanic battery has been ordered to be sent to Sunderland, and the effects of this most powerful agent are to be ascertained. The experiments of the late Mr. Finlayson, at Ceylon, though too limited to warrant any general inference, were certainly such as to justify farther trial: in one of his patients, who was "moribund," a galvanic current from a small battery was passed through the chest, the man immediately revived, and ultimately recovered. The same gentleman also states, that in two out of three cases, the functions of the lungs appeared to be restored by stimulating them with ammonia, volatilized so as to impregnate the atmosphere with its fumes.

We earnestly recommend a trial of injecting medicated solutions into the veins, particularly some of the neutral salts, as muriate of soda. No one who ever saw a leech disgorge its black blood upon salt can fail to have observed its instant conversion into a brilliant scarlet. That the change of colour carries with it a corresponding change of character, we do not venture to assert; but it is at least worth ascertaining; and we think that the views of Dr. Stevens, as to the effect of salts on the blood, to which we have repeatedly called attention, ought to be put to the test as speedily as possible. It affords no mean claim to the investigation of these doctrines, that a man of Dr. Prout's high character should have declared the essay containing them, and which was published in this journal, to be one "which, spite of

some imperfections, seems to contain the germs of discoveries of the last importance to mankind."

CONTAGIOUSNESS OF CHOLERA.

SOME of the gentlemen at Sunderland, who doubted the contagious nature of cholera, do so no longer. One of them informs us, "that the contact of the body after death is more powerfully infecting than during life."

CHOLERA RETURN.

THE total number of cases of cholera at Sunderland, from the 6th of October to the 30th of November, was 319; of whom have died 97; being, in fact, almost all of those in whom the disease assumed malignant characters.

CHOLERA *versus* LIFE ASSURANCE.

WE alluded, now some months ago, to the curious circumstance, that while the cholera appeared in Europe, though yet at a distance, the number of persons in this country who insured their lives underwent a sensible diminution, a circumstance which we attributed to the apprehension, that if the malady should prevail extensively here, the contracting parties would be unable to meet their engagements. That the value of human life will be altered to a greater or less extent, is quite obvious; but we understand that some of the Assurance Companies regard themselves as secured by a bye-law, which provides, that in the event of any plague or pestilence prevailing in this country, the heirs of persons dying of such malady shall be entitled to receive only a certain proportion of the sum assured. We have been informed, that at a meeting of one of the most opulent of these societies, held a few days ago, the existence of such provision was alluded to:—if so, we crave leave to ask, how far a bar-

gain will be held binding in law, to which both assurer and assured were not parties? We remember that Lord Eldon, at the time of the bubble mania, when so many new Companies were started, distinctly stated, that they might make what bye-laws they pleased for their own internal regulation, but that nothing involving the interests of the assured would be held good in a court of law, except what appeared on the face of the policy. The question may become a very important one.

CHOLERA AT HAMBURGH.

WE have been favoured with the perusal of an account of the irruption of cholera at Hamburgh, by Dr. Fricke, a physician of some repute in that place, which has been transmitted to the authorities in this country.

The writer professes that his object is to shew that the disease was not imported, but originated in local causes, not of a very obvious nature, nor easily admitting of description. As a consequence of this position, it follows that the malady cannot be exported, and therefore that "the onerous quarantine" ought to be abandoned, more especially as regards the admission of Hamburgh vessels into foreign ports. Such are the declared objects of the writer; how far his inferences are warranted by the facts detailed, we shall leave the reader to decide.

No cases were known to exist nearer than 30 miles from the town, till it appeared within its walls—on the 5th October. Reference, however, is made to a case anterior to this, which deserves to be mentioned. A sailor belonging to a vessel performing quarantine died of a bowel complaint, into the history of which a medical committee was appointed to examine. They found that the individual had been received on board at Wittenberg on the 7th of September, at which time he had a looseness, but not to such an extent as to prevent him from attending to his business. On the 23d he became much worse, and died on the 2d of October; the case, however, was declared to have been one of "chronic diarrhœa." The vessels alluded to was discharged from quarantine, and admitted into the harbour among

the rest of the shipping on the 5th of October. The first person who is stated to have been attacked with cholera was one Peter Petersen, a drunken pauper, who lived partly by begging, and partly by selling things about the streets. He was in the habit of remaining away from his lodging during several days and nights together, and was absent on one of his wanderings on the 20th and 21st of September, during which time it is first stated that he had visited none of the shipping, but subsequently an exception is made with regard to certain barges laden with fish, potatoes, and cabbage, the latter having evidently come down the river from the interior. This person was taken ill on the 5th of October, and died next day. He lived in a cellar in Nicholas-Street, a narrow lane, within eight hundred feet of the harbour. The house appears, from the account, to have been a large old building, the lower part of which, under the level of the street, was occupied by a little colony of vagabonds of both sexes, who lived promiscuously; there were forty-one of them in all, and of these eight were foreigners.

The second case occurred in the person of a female, residing in the same cellar, in which, by the way, seven persons slept. She had not been out for several weeks, till the 5th, when she went to assist in digging potatoes: on her return, Petersen being ill, she attended him as nurse. She was seized with cholera on the evening of the 7th, and died on the 8th. The manner in which the obvious communication of the disease in this case is attempted to be got over, is a curious illustration of the extent to which men will sometimes shut their eyes, that they may not see what would otherwise be most conspicuous. The woman, we are gravely told, had no connexion with Petersen, "with the exception that she attended him as nurse during his short and rapid illness"—(als dass sie solchen bei seinem kurzen Krankenlager gewartet hatte.)

The third case was that of a waterman, named Somers, the particular friend and companion of Petersen, who had accompanied him in his wanderings: he was seized on the 7th, and died on the 10th. This patient, "on the night on which Petersen was taken ill, had slept with him, and subsequently attended upon him during his illness."

On the 8th of October, two

more cases occurred in the same cellar. From this time cases began to appear in other individuals, dwelling in the same neighbourhood. Thus, on the 8th, a person named Neuer was taken ill; he had worked in the dock-yard on the two preceding days. On the same day one of the crew of the *Atlas*, a vessel lying in the harbour, was also seized with the malady; and three other cases occurred in the vessel within ten days. On the 9th of October the presence of the disease at Hamburg was declared in an official document signed by the principal medical men of the place; and on the 14th a proclamation was issued by the magistrates, calling upon the people to bear the visitation with fortitude, and not to aggravate the evil by any attempt at concealment: "a mere denial of the disease being among us (say they), cannot alter the views of foreigners as to its existence, but may facilitate the spreading of the malady, and prevent that immediate assistance which the sick require from being rendered." Let the good people at Sunderland take the hint.

Upon the whole, we have never met with a more curious document. The facts are interesting, and seem to be trust-worthy, inasmuch as they make directly against the purpose of the writer; so that he cannot be supposed to have admitted them otherwise than because they were too notorious to be denied. The chain of connexion between the first case and those which immediately followed, is so obvious and unequivocal, that, unless we had seen Dr. Fricke's account, we could not have believed it possible that such facts could have been adduced by any man, to prove that the disease was merely dependent upon local causes—had not been communicated to the Hamburgers from without, and could not be transmitted by them to others;—yet, so it is.

A PRETENDER AT SUNDERLAND.

THE good people of Sunderland are, some of them at least, very odd personages. A correspondent of the *Times*, in Monday's paper, begins his epistle in this inflated way:—

"This is an age of pretenders, and to guard against them I think it proper to bring to your recollection, that *I* was the first observer who discovered, or at least made the fact publicly known, that

the different forms of cholera at present spreading in Sunderland were one and the same disease—that disease being the Indian cholera!" Prodigious! the discovery is worthy of a Jenner, or a John Hunter; but what, in the name of common sense, is the meaning of the first part of this pompous announcement? That as *pretenders* (this is our conception of it) *are abroad*, our best preservative against them is, *to recollect* that the writer in question was *the first who discovered* that the cholera at Sunderland was the Indian cholera! If we are right, then, once more we say prodigious!—but evidently the sentence, with that signification, is somewhat elliptical: it will be but a lame and impotent recollection, if we do not please to remember at the same time, that he who discovered the disease may also have discovered the remedy.

But proceed we to another sentence. Our great discoverer, after thus warning us of the present existence of pretenders, and jogging the Editor's memory as to the great claims of a certain person, presumes to make a thrust at Dr. Barry and *his pretensions*. "Dr. Barry, who has been here for some days, did not, *it is said*, entertain any suspicion of the circumstance, until he heard of *my opinions* yesterday, and I am informed that *they excited his surprise*." So well they might, notable mare's nest as they are! But, of course, in this gentleman's estimation, Dr. Barry is no more than one of the many pretenders who are abroad; and this brings us to issue with our letter-writer on the matter of fact. Did Dr. Barry really entertain doubts about the identity of the disease at Sunderland and what he saw at St. Petersburg, until surprised by our discoverer's opinions? We cannot take credit to ourselves for being enabled to set this matter right by an exclusive statement, for the learned physician's letter on the subject is now before the public; but we *know* that Dr. B. had not seen above two or three cases of the Sunderland cholera when he was convinced of its genuine character, and immediately apprised the authorities here to that effect: his words were, "it is identical with the disease of which Dr. Russell and myself saw so much at St. Petersburg." That the sapient correspondent of the *Times* was not acquainted with Dr. Barry's convictions, we can readily conceive; but the insinuation conveyed in the epistle is grossly

presumptuous and absurd, even though it is conveyed cautiously under the form of an *on dit*.

After some more conceited nonsense of the same sort, our notable discoverer favours us with the announcement, that he thinks, with certain philosophers, that "every thing has two handles—a right one and a left:" we apprehend that the gentleman has taken the trouble of going down to Sunderland to catch hold of the wrong handle—at least, in the present instance, he has acted with consummate awkwardness; and his disguise drops off but too egregiously before he leaves us. In the last paragraph he slips in a piece of vile puffery about a "Mr. Kennedy, a London practitioner, the author of a work on cholera;" and this we take to be the key to the whole production. That the person here alluded to is disappointed in consequence of not being employed by the Board of Health, is by no means impossible, as we find him still *unattached* in Sunderland. But what in the world, even though Mr. K. were "a London practitioner," have his opinions *in that capacity* to do with the question one way or other?

DR. BARRY ON CHOLERA.

SHORTLY after the arrival of Dr. Barry in Sunderland, he requested a meeting of all the medical gentlemen of the town, and in consequence a most numerous assembly was convened in the Exchange rooms. The high reputation which Dr. Barry had so justly obtained was not lost upon the faculty of the town, and at the meeting much valuable information, particularly as regards cholera, was accordingly elicited.

Dr. Barry having detailed the symptoms of the Russian cholera in a very lucid and graphic manner, (viz. the vertigo, the prostration of strength, the peculiar evacuations from the stomach and bowels, the spasms, the collapsed countenance, the whispering voice, the blue skin, the cold tongue and respiration, and the arrest of the circulation) declared that the Sunderland epidemic and the Russian cholera were the same disease, the diagnostic marks being so prominent as to render it, when once seen, not easily to be mistaken.

Dr. Barry, when speaking of the pathology of the disease, stated that in

examinations after death he had generally found congestion of the great vessels, and very frequently effusion of blood in patches beneath the mucous membrane of the stomach and intestines; the gall-bladder always distended with bile; the urinary bladder contracted, and containing either nothing, or a minute quantity of whitish fluid; and the intestines void of any feculent substance; but the most remarkable morbid appearance, and that to which he would attach the most importance, was the phlogosed and softened state of the spinal marrow, which in a greater or less degree was always present.

With respect to the treatment, he would recommend full vomiting, in order to emulge the gall-bladder, which might be produced by a strong solution of common salt in water, given in doses of six ounces. Warm, dry applications to the skin, and especially patient and continued friction, he had found very beneficial; whilst moist warmth, all kinds of vapour and water baths, he considered worse than useless. Bleeding, as well as large doses of either opium or stimulating liquors, were dangerous in the collapsed state, when the powers of life were reduced to the lowest ebb, and consequently easily annihilated; but when re-action was beginning to take place, or previous to the state of profound collapse, he believed that blood-letting would be of benefit to the patient. A practice which he would strongly recommend in this country (should the disease unfortunately progress,) but which circumstances would not allow him to use on the continent, was the application of the actual cautery to the back, opposite the lower dorsal and upper lumbar vertebræ: this had been done with success by a celebrated continental physician, and he (Dr. Barry) thought it a mode of treatment highly worthy of trial.

In answer to a question put to him, Dr. Barry stated, "that he had seen no case of *common* cholera at Sunderland."

TEMPERATURE OF THE HUMAN BODY.

SOME years ago, Dr. John Davy made a set of experiments with a view of ascertaining the changes, if any, which the temperature of the body undergoes

in different parts of the globe, and the result was, that some, though but a slight elevation, occurs in warm climates, and a proportional decrease in cold countries. These experiments were lately repeated by M. Regnaud, of Paris, during a voyage in the eastern hemisphere; and as the thermometers used were compared by M. Arago with those of the Observatory in Paris, their accuracy cannot be questioned. Four sets of observation were made in the torrid zone, and three in temperate climates; while all were made on the same twelve individuals, robust and healthy men, fed, clothed, and lodged, in the same manner. In $10^{\circ} 4'$ north latitude, the air being at 79° of Fahrenheit, the average temperature of all the twelve was $99\frac{1}{3}$ degrees; in $36^{\circ} 10'$ south latitude, the atmosphere being $62\frac{1}{2}^{\circ}$, the average temperature of the men was $98\frac{2}{3}$ degrees; under the line, and with an atmospheric heat of 86° , the animal temperature was 100 degrees. In latitude $7^{\circ} 1'$ south, the air being at 86° , the body was $99\frac{1}{2}$ degrees; and, again, the air being at $62^{\circ}\frac{1}{2}$, the body was at 99 degrees, and the atmosphere rising to 79° , the body rose to $99\frac{1}{2}$ degs. Thus the atmospheric range was from $53\frac{1}{2}^{\circ}$ to 86° , which produced a variation in the animal heat of only one degree and a half.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Nov. 26, 1831.

DR. SIGMOND IN THE CHAIR.

Nature and Treatment of Cholera.

DR. JAMES JOHNSON said, that with a view of economizing the time of the society, of introducing a systematic mode of discussing the subject, and more particularly with a view of avoiding the necessity of repeated explanations, and preventing misconception, he had taken the liberty of throwing his observations into a series of short propositions, distinct from each other, by which any member, or members of the society, would be enabled to discuss any one particular point without diverging into irrelevant matter. The propositions, which the doctor read from a written copy, were as follows:—

I.—That in epidemic cholera, as in most other epidemics, a poisonous or sedative principle, whether originating in the earth, or emanating from animal or vegetable substances, strikes a predisposed individual, and

after an uncertain period of incubation, produces a train of phenomena forming the subsequent disease. In sporadic cholera the diffusive power is absent; but when the common exciting causes are strong, and the subject highly predisposed, severe or fatal cases will occur which cannot be distinguished from those of epidemic cholera.

II.—The effects of the choleric poison exhibit a great analogy to those produced by the virulent contagion of typhus, and the concentrated miasmatic exhalations that give rise to malignant fevers, remittent and intermittent, such as we see in Batavia and other highly malarious places.

III.—This poison shews its effects, according to the evidence of our senses, first on the nervous system, as evinced by the prostration of strength, by the affection of the head, by the absence of the secretions; and, in fact, by a depression of the whole of the sensorial functions as well as those of organic life.

IV.—The secondary effects of the choleric poison are shewn in the vascular system; the circulation recedes from the surface, the blood accumulates in the internal organs, the decarbonization and calorification cease or are greatly diminished, the temperature of the body falls to that of the surrounding inanimate substances, paleness is changed to blueness, and the functions of the ganglionic system of nerves seems to be suspended, if not annihilated.

V.—It is at this period that nature appears to make violent, but too often unsuccessful, efforts to restore the balance of the circulation, and to re-establish the secretions by sickness and purging, the ejected fluids being exudations rather than secretions.

VI.—If nature do not succeed by the above-mentioned efforts in restoring the circulation and secretions, and consequently oxygenation and calorification, these efforts themselves prove auxiliaries to the choleric poison in destroying life.

VII.—We are not in our present state of knowledge certain whether the spasms be merely the effects of the poison on the nervous system, or an effort of nature to resist it; but they, like the sickness and purging, if not immediate, tend ultimately to excite the powers of life.

VIII.—If nature, by which I mean the constitution, whether with or without aid, be able to resist the first or depressive shock of the poison, and institute a re-action of the system, that re-action, in a great majority of cases, becomes a fever, exhibiting a new train of phenomena, and demanding a different treatment. If this view be correct, it would lead to the inference, that what is understood by cholera sometimes constitutes the first stage of choleric fever.

IX.—If re-action, if restoration of the circulation and secretion, and oxygenation,

do not take place, the patient dies in a state of asphyxia, the intellectual powers often remaining but little impaired till the last glimmer of the lamp of life is extinguished. This has been often witnessed in concentrated miasmatic fevers within and without the tropics.

X.—Pathology. All the changes which present themselves in the dead body are, in my opinion, effects, not causes of the disease, with the exception of the congestion of black blood in the internal organs, which is almost the only phenomena observable when cholera terminates fatally in a few hours. The traces of inflammation in various organs after death are connected with the reactive fever rather than the cholera which precedes the fever.

XI.—Treatment. As we have no means of expelling or neutralizing the poison, we can only endeavour to counteract its effects, and assist nature in her movements.

XII.—The primary or essential indication is to restore the equilibrium of the circulation. If that equilibrium be effectually restored, secretion, calorification, and oxygenation follow.

XIII.—The balance of the circulation is to be restored partly by internal, partly by external means, but always by several means simultaneously employed at the very earliest period of the disease.

XIV.—Venesection may appear a desperate remedy, but we have a desperate disease to combat. I proposed this measure many years before the epidemic broke out, and it has been adopted to a very considerable extent both in Asia and in Europe; and I proposed, and would still propose, venesection with a two-fold view; first, to relieve the heart and internal organs from a portion of that deluge of black blood in which they may be said figuratively to be drowned; secondly, to turn, as it were, the tide of the circulation from the centre to the surface of the body. This measure I would chiefly confine to the young, the robust, and the previously healthy, and in them contemporaneously with, or soon after the measure which forms my next proposition.

XV.—The first internal remedy which I propose, both in aid and in imitation of nature, is a stimulant emetic, as an infusion of mustard-seed, or, what perhaps would be better, sulphate of zinc. I propose this from a conviction, founded on observation, that of all the means which nature or art can bring into operation, the act of full vomiting is the most powerful, driving the blood from the internal organs to the surface of the body, and it is also the most efficacious means of exciting the secretion in every glandular structure of the living machine. Nausea and retching are quite different in their effects from the operation of full vomiting. Nausea and retching depress

the powers of the heart and nervous system, and prevent the blood from flowing to the surface. Full vomiting impels the circulation with great force into the superficial vessels, for it is extremely difficult to stop the flow of blood from the orifice of a vein during vomiting. I have seen the blood come from a vein under such circumstances with all the characters, or at least all the appearance, of arterial blood. This proposition is well exemplified by sea-sickness, of which I have had painful personal experience. An unfortunate landsman bears a close resemblance during the first storm he experiences at sea to a man with cholera. He staggers about the deck, striving to keep down the rebellious heavings of his stomach, but he cannot succeed, up it comes; and during the first vomiting, I have seen the blood gush from the mouth, nose, and eyes of the sea-sick sufferer. From being actually blue with nausea, his face becomes red with vomiting; but the cause of the sickness still continuing, he ultimately becomes pale and exhausted. He is like a man who takes a fresh dose of emetic tartar after each paroxysm of vomiting, and the wonder is that he does not die: I have known some die of it. It is curious that Cælius Aurelianus, who gives the best ancient account of cholera morbus, places sea-vomiting among the causes of that disease. It is but justice to state that Mr. Boyle proposed full vomiting in epidemic cholera ten years ago; and I have the best authority for recommending this, because when it was pursued on the continent, it was eminently beneficial.

XVI.—As soon as vomiting has produced its salutary effect on the circulation, or has failed to produce that effect after a fair trial, I would propose diffusible stimuli, with calomel and opium, but not in immoderate doses. Brandy and laudanum, as being most readily procured, and the least likely to be loathed, are perhaps the best; but the choice of stimuli must be left to the practitioner, and the danger of inducing subsequent inflammation should be constantly borne in mind. Calomel alone would probably be the most successful after the emetic.

XVII.—The remedies above mentioned, in moderate but efficient doses, seem to impart vigour to the heart and nervous system through the medium of the stomach. While they mitigate the spasms, and restrain the injurious exudation of fluids from the intestinal canal, the mercury changing these exudations into secretions.—*Qu.* Would not the inhalation of oxygen gas be beneficial?

XVIII.—The external remedies are three—heat, friction, and counter-irritation. These three means should be employed, not only simultaneously with respect to each other, but contemporaneously with the internal remedies. They should always be so employed, that the patient may not be suf-

ferred to throw a single voluntary muscle into action : every muscular movement, even that of sitting up in bed, is prejudicial, or absolutely dangerous during the exhausting orgasm of cholera. An apparatus, permitting the application of heat, friction, and counter-irritation, without the necessity of muscular exertion on the part of the patient, will be shewn to the society. As the cramps and spasms are chiefly confined to the extremities, would not firm compression by bandages mitigate them?

XIX.—Prophylaxis. Considering myself, as well as every member of this society, bound to abstain from all discussion on contagion, I shall consider this subject in four words—temperance, cleanliness, ventilation, and fearlessness: in fine, the presence of all those things which tend to preserve general health, and the avoiding of all those causes which predispose to common diseases.

He (Dr. Johnson) had thus endeavoured to throw into a series of propositions the chief points for discussion. He solemnly protested he would not defend a single proposition for the sake of argument or victory, but renounce all, or each of them, the moment he was convinced of their or its instability. The learned doctor then exhibited the apparatus of Mr. La Baume, for applying hot air or vapour to the surface of the body.

Mr. BOYLE had visited India; and remaining there for some time, he had an opportunity of seeing a great deal of cholera. He had great opportunities of making post-mortem examinations, in the course of which he endeavoured to ascertain the cause of the absence of bile. The general appearances discovered by him were already on record, and consequently he would now merely remark, that, in all fatal cases of cholera, no bile appeared, whereas in every favourable case it did. He sought for the cause of that phenomenon in the biliary ducts, and frequently found them so much obstructed as to experience a difficulty in passing a probe. The gall-ducts were distended with dark-coloured bile sufficient to obstruct them, independently of the spasmodic action which there was reason to suppose existed contemporaneously. The unsuccessful application of the various remedial agents that were recommended, together with the facts he had just stated, induced him to believe that, if a remedy could be administered which would produce bile, the appearance of which was always salutary, and the absence of which always indicated a fatal termination, it would be the best agent that could be employed. He also found, contrary to general opinion, that there was not such a degree of vomiting and purging as was generally imagined in the *worst* cases of epidemic cholera; on the contrary, that where those

symptoms occurred, together with violent spasms, the patients generally recovered. If the patients were very bad, there was a great collapse; the powers of life seemed to be destroyed, or paralysed, at the moment of attack. If patients merely made unsuccessful efforts either to vomit or to unload the alimentary canal, they generally died. If a patient, when interrogated, merely said that he felt unwell, but could not describe the nature of his case, fatal consequences most probably ensued; whereas, if, on the contrary, violent action occurred, accompanied with violent spasm and serious complaints, and sufficient power remained to enable him to discharge the diseased matters, that patient generally recovered. He thought those observations worthy of remark, because he presumed that, if a gentleman who had not previously seen the disease were called to enter a room in which two patients were lying in the circumstances he (Mr. B.) had just described, he would most likely pronounce an inaccurate prognosis. It was from those circumstances that he was led to exhibit emetics, and in every case where he had an opportunity of doing so, they proved successful. He did not wish to attach more importance to that fact than it deserved, but he understood, from good authority, that emetics had proved highly serviceable on the Continent; certainly not in every case, but they had been found to be the most successful remedies. He was first led to introduce the practice from analogy, and few cases which he had treated by emetics and other auxiliary means proved fatal. Having thus stated the reasons why he adopted emetics, he would now offer a few remarks upon other remedies. [Mr. Boyle here made some remarks on bleeding, and afterwards on frictions and other external applications.] As to the internal remedies, in addition to an emetic, he thought that benefit might be derived from calomel, opium, brandy, and ammonia and aromatic confection. It was not wonderful that calomel should have been brought under the notice of the profession as an important remedy in cholera, in consequence of its efficacy in the treatment of diseases generally in tropical climates. In bad cases of cholera, however, he had never seen calomel produce any effect whatever, and, in post-mortem examinations, he had found it adhering to the mucous membrane of the stomach and the duodenum unaltered. Ammonia he looked upon as the most important stimulus with which he was acquainted in the depressive stages of all diseases, whether acute or chronic. Compound spirits of lavender he considered an excellent stimulant, combined with brandy punch. It was impossible for him to follow Dr. Johnson's propositions in detail, but there were two or three points to which he would allude, and the first related to cramps. Having seen a

number of patients at the moment of being taken ill, without cramps, he did not think that they were a cause, but a symptom of the disease. He did not believe that all the appearances observed in post-mortem examinations were causes, but that some of them were consequences of the affection. The distention of all the interior vessels he believed to be consequences; but the obstruction of the bile ducts, and the dark or green colour of the bile, he looked upon as the immediate causes of the affection.

DR. GREGORY remarked, that he thought it would contribute to a clearer understanding of the subject, if the *nature and treatment* of the disease were discussed separately; and he recommended, that the society should devote itself, in the first instance, to the question of the *identity of the common with the Asiatic cholera*. It was admitted on all hands, that the disease now prevailing at Sunderland was identical with that which had prevailed in Russia and in India subsequent to 1817; but it was still a matter of controversy, whether it was the same disease as that described by *Sydenham* under the title of cholera, or as that which had occurred in India prior to 1817. To determine these points was not a question of idle speculation, for upon their decision it depended, how far we could benefit by the experience of former times, in regulating our treatment of the present epidemic. For himself, he had already avowed his conviction, that the Asiatic cholera was truly a *nova pestis*, unlike any disease hitherto described under the same name. Still he thought the question open to investigation, and peculiarly fitted for discussion in this society. For the present, he merely threw out this suggestion with the view of guiding the society into a profitable path, reserving, to a future occasion, a more extended examination of the question.

MR. SEARLE said, that cases of the disease which had occurred at Sunderland had been submitted to his inspection, and he felt no hesitation in stating that it was the same as that which he had seen at Warsaw. His observation was not founded upon any of the symptoms, but upon post-mortem examinations.

DR. GILCHRIST made some observations.

DR. COPLAND remarked that Dr. Johnson had taken for granted, in his first and second propositions, that the present pestilence was identical with the severe forms of cholera frequently met with in warm climates, or in warm and moist seasons in temperate countries,—an inference which the symptoms of both diseases, and the experience of many able observers, did not warrant. He stated that he had, on the previous evening, when called upon, referred to the preliminary symptoms, the symptoms observed in its course, and to the consecutive phenomena and terminations of this pestilence, as fur-

nishing decided evidence that it is altogether distinct from the disease called common and spasmodic cholera, and the marks of distinction he was still ready to show and maintain. As to the pathology and treatment of the disease, as stated by Dr. Johnson, he had but little to remark, and scarcely any thing to object. He would only observe that the pathology, even as laid down by Dr. Johnson, furnished striking evidence of the difference existing between this pestilence and common or spasmodic cholera. His views respecting the propriety of combining the means of cure, and directing them simultaneously into action, as well as his recommendation of emetics and bloodletting, very nearly met those entertained by Dr. C. himself, but that much would depend upon circumstances as to the extent to which bloodletting should be carried, and occasionally as to the propriety of omitting it altogether. He conceived that the different grades of the disease, as well as its different periods or stages, required a modified treatment, and in this, he stated, that he was borne out by the experience of Dr. Keir, of Moscow, as detailed in a valuable letter, the perusal of which had been granted him by a friend (Mr. Craigie, Dr. C. informed us) now present. According to the experience of this gentleman, the most intense grade and advanced stage of the disease did not admit of bloodletting; whilst, in the less severe cases, and in the more intense cases when they came immediately under treatment, the advantage derived from the practice was decided. As to the superiority of warm or hot air over the warm or vapour bath, he expressed his belief; and he could recommend, from an extensive experience of the practice in analogous states of the disease to the present, the turpentine fomentations, and the other external measures which he had detailed in a previous number of this journal. The probable advantages of inhaling stimulating and oxygenated gases, he remarked, had been recommended by various writers, and, as the question in which the exciting cause of the disease made its invasion of the frame was evidently the lungs, and, as this organ was paralyzed by its impression, the propriety of trying this mode of medication was evident. Respecting the use of calomel in the disease, he remarked that its utility was undoubted, and that it should be remembered that, when the powers of life were reduced very low, it had no effect unless combined with stimulants, particularly camphor and ammonia.

DR. WEBSTER thought that the question of Dr. Gregory was of great importance, because if they could establish the identity between the disease as it occurred in India, and was now prevailing in Sunderland, and as was frequently seen prevailing in this country, he considered that a great step

would be gained towards arriving at a knowledge of its proper treatment. He had not seen the disease in Asia, but he had seen cholera as it frequently prevailed in England, and as it had prevailed in the southern parts of Europe, and to him it appeared to be the same disease, though it was no doubt modified by the peculiarities of climate in which it occurred, as also by the habits of the individual affected. The ague, which occurred in the fens of Lincolnshire, was the same complaint as that which affected the inhabitants of the Pontine Marshes, or the community of more southern regions, varied, no doubt, by particular circumstances. As facts, however, were of greater importance than declamation on this subject, he would refer the meeting to a description of spasmodic cholera as it occurred in India, and the document to which he would call their attention was a paper contained in the fourth volume of the Medical Transactions of Calcutta, by Mr. Wood. [Dr. Webster here, amid some interruption, read two cases, which terminated favourably, and contrasted them with others, which terminated unfavourably.] His object in stating those particulars was to prove, that the disease, described as cholera spasmodica, was a complaint which had always existed in this country, and had been well described by Sydenham, and as this was the case, he trusted the public anxiety would be relieved. He had seen a letter from Vienna within a few days, describing the disease as it occurred there, and the account given was, that, when the disease first broke out, many fatal cases occurred, because the treatment was not understood, but afterwards public fear was allayed. Gentle emetics were given in the first instance, and the vomiting was directed to be kept up by camomile tea. Whenever that was followed by perspiration, and by a copious discharge of the contents of the stomach, particularly with bile, the patients generally recovered. He (Dr. W.) thought it right to state that fact, in corroboration of what had been advanced by Dr. Johnson and Mr. Boyle. Salt soup was also recommended; ipecacuanha emetics were found to be the best.

Dr. Thomson could not accord with the opinion delivered by Dr. Webster, that the cases detailed by him, and others of a similar nature, were identical with the disease which had lately reached the British shores. As far as he could form an opinion, from the perusal of the Indian reports, and other writings of those who have seen the disease as it appeared in India, there seems to exist a decided difference between it and the most virulent cases of the spasmodic cholera known in this country. Even in the description of Sydenham the distinction is obvious. In one particular, the presence or absence of bile, the diagnosis of the disease now spreading, is well marked. The most striking feature of the present malady, its communicable

character, is evidently one which had never been observed in the ordinary Indian cholera; and, consequently, when the present disease broke out at Jessore, the inhabitants saw sufficient in it to alarm them, and rapidly fled from it. It is, in his opinion, impossible to confound the two diseases; and probably much of the diversity of opinion which has unfortunately prevailed in the profession, may have arisen from the name imposed upon the cholera, and its similarity in some of its features to the ordinary Indian cholera. With regard to the symptoms, the most important, the state of collapse, is that which almost exclusively demands attention. There seems to be a complete paralysis of the nervous system, which, as it were, arrests the function of circulation, and consequently prevents that change from taking place in the blood which results from its passage through the lungs. The blood is accumulated on the heart and large vessels, owing to the vital energy of the circulating agents being nearly destroyed; and this readily explains the pale, cold state of the surface; the absence of bile in the alimentary canal; the coldness of the breath, and many other symptoms. The effect closely resembles that which follows the bite of some of the most venomous serpents, or the action of powerful sedative, vegetable poisons, such as the *upas antiar*, on the living system, that Dr. Thomson could not help believing that, in whatever manner the disease originated, it was now produced by the exhalation of a most powerfully sedative virus from the bodies of the sick, which, applied to those of broken-down constitutions, or otherwise predisposed to receive it, operates by an immediate impression on the nervous system. It is, in his opinion, this paralysis of the nerves which induces all the other symptoms; and, therefore, the first object of the practitioner should be, to sustain the habit under its impression, and to endeavour to rouse the powers of the circulation. The question is, how is this to be accomplished? Dr. Thomson deprecated the use of the lancet for this reason, that the congestion is a consequence of the paralysis of the nervous energy, not its cause; and he could not comprehend, even if blood could be obtained in such a state of the habit, what advantage would be derived from it, as long as the paralysed state remained. If the heart were struggling to expel its contents, and could not accomplish it, then he would accord with the propriety of blood-letting, but not otherwise. He believed, that in those cases which had been benefited by it the bleeding had preceded the state of actual collapse. He strongly recommended stimulants in this state, such as ammonia and volatile oils; and effects had been recorded of the power of the former, in the experience of some of the Indian practitioners, which were almost marvellous. Dr. Thomson concluded by remarking, that any thing which he could

offer to the Society on this subject was of little value, as he had never seen the disease: let him once see it, and then his mind would be soon made up as to the manner in which it ought to be treated.

DR. WHIRING, in conjunction with all his medical brethren, had had several cases of cholera during the last year, but he had not had one fatal case. He had seen cases very severe—he had seen cases lying in a state of collapse, almost in a moribund condition, but these patients recovered. That was not the case, however, with the malignant form of the disease, as it occurred abroad and at Sunderland; there the patients died, and consequently he saw in that circumstance a certain degree of difference in the affection. If that were sufficient to establish a distinction in the two cases, then the question inevitably arising was, "Is there any difference in the mode of treatment to be adopted?" If that question received a negative reply, then where was the necessity of making a distinction between the diseases? He might be allowed to say that he believed they were obliged, in this disease, to be guided by principle; for they did not know wherein the essential nature of cholera consisted. It had been remarked by Dr. Johnson, that there was an impression made on the nervous system; but what that was they knew not; they only knew that the effect produced by the impression was subsequently manifested principally through the medium of the circulation. If, then, that were the case, they must prescribe for the symptoms of the disease; for at present they had no specific for it. Now, what were the symptoms? They were such as were seen in many cases, not only of cholera, but of typhus fever, and occasionally in other diseases where there was a great collapse of the system, an overloaded condition of the heart and large blood-vessels, and a deficiency in the capillary circulation. If such were the case, why should they make a difference in the treatment? They acknowledged they did not know the nature of the disease—they acknowledged they had no specific for it—and therefore let them take the symptoms and prescribe for them, whether they occurred in typhus fever or in cholera. It was in that way that judicious medical men were now looking at the treatment of cholera—it was in that way that they had treated all sporadic cases—it was in that way they had treated typhus fever, and it was that way Dr. Mackintosh had been treating severe cases of ague in the cold stage, when that stage proceeded to an extreme degree. He must acknowledge, however, that he did not accord with some sentiments which had been expressed respecting blood-letting. It had been said, that, in the severest cases, they ought not to bleed. He would only argue analogically from what he had seen in severe cases of typhus fever, where the system was in a state of congestion. It was in

the severest cases that the remedy was the most efficacious. It struck him that, in opening a vein in the severest cases, they were doing more good than in those instances where the disease assumed a milder character. He would prefer the external jugular. The external application of heat ought clearly to be had recourse to; but he could not think that the internal exhibition of stimulants was always allowable; for two things were greatly to be feared as the result of the means employed—namely, inflammation of the stomach and bowels, and general excitement, in some very severe cases. If mercury were recommended, he should be glad to know on what principle? If it were small doses, to excite the liver, it might be of service in time, but he thought not immediately. If it were exhibited for any other purpose, then he should like to know how it acted.

MR. HUNT made some observations with regard to the disease at Sunderland.

DR. O'SHAUGHNESSY moved that the debate be adjourned, and gave notice that, at the next meeting, he should take the liberty of stating to the Society the results of some chemical investigations he had made, connected with this disease.

The resolution having been seconded and carried, the meeting was about to disperse, when

DR. JAMES JOHNSON rose, and spoke at some length on the question of identity. It had been stated, and argued, that the cholera morbus which broke out at Jessore in 1817, and not there only, but at several other places contemporaneously, was not identically the cholera as it appeared previously to that period. The general argument was, that it had never been epidemic before, that it was only sporadic. Now the fact was, that, at Surat and the neighbourhood, sixty thousand persons were carried off by one visitation in the year 1760. That was certainly a curious specimen of sporadic cholera. The symptoms which then occurred were precisely the same as those manifested at Jessore in 1817. Within the last week a case had occurred, which was actually submitted to government, and caused considerable alarm in their minds. [The doctor here detailed the particulars of a very severe case, with cramps of the limbs and blueness of the surface, which had occurred at the St. James's Workhouse.] There was something in the epidemic that made the cases more severe, more numerous, more fatal, and consequently characterized it, but the individual features of the cases were the same; and at the time he did not feel justified in stating that the patient, to whom he had just alluded, did not labour under Indian cholera.

A desultory conversation then ensued, several gentlemen complaining that Dr. Johnson had been allowed to address the meeting after Dr. O'Shaughnessy's motion was carried; in the midst of which the meeting

was adjourned until next Saturday, on the understanding that the debate on the nature and treatment of the disease was to be introduced by the mover of the adjournment.

PORTRAITS OF PROFESSIONAL MEN.

ENGRAVINGS from two cabinet portraits of Mr. Abernethy and Sir Astley Cooper have been sent us. The likenesses and execution in both are excellent; and the pupils of these distinguished teachers will recognise their old masters in their happiest aspects.

PHYSICIANS TO MARYLEBONE INFIRMARY.

DR. HOOPER resigned the Marylebone Infirmary some weeks ago, and is said to have recommended Dr. Ager as his successor. Dr. Hooper had a salary of 200*l.* per annum; and as the appointment was otherwise looked upon as a good one, half the physicians in the parish became candidates for it. The ardour of the competitors, and the extreme disinterestedness evinced by some of them, led the guardians of the poor to discontinue the gratuity altogether, and to elect two physicians instead of one. Such is the injurious effect upon our profession of competition carried to excess—the physician is *not* thought worthy of his hire. The choice fell upon Dr. Hope and Dr. Sims.

DR. GILCHRIST.

WE have received a letter from this gentleman in which he strongly denies having been influenced by any personal feeling in the remarks he made at the Westminster Medical Society on the 19th instant, relative to the disputed point of the contagiousness of the Yellow Fever at Gibraltar.

DR. ELLIOTSON'S LECTURES.

A CONTEMPORARY, jealous—and not without cause—of this journal, has inserted a notice to the effect that Dr. Elliotson's lectures cannot be completed "for two or three years," and that *his* plan is to make the volumes of each year contain complete sets of lectures. We have to inform our readers that *our* plan is in this respect precisely the same, and that, as heretofore, the volumes of each year shall be made complete in themselves, and independent of the others.

HOT AIR AND VAPOUR BATHS.

NUMEROUS methods of applying hot air and vapour baths to the surface of the body have recently been submitted to us. Most of them are on the principle of Dr. Gower's Sudatorium, more or less modified. Among these, Mr. La Baume's, and Mr. Green's baths, are particularly deserving of attention, being portable, and easy of application. Nor must

we omit to mention the bath for hot air or vapour made by Mr. Rippon, of Castle-street, East; it goes into an extremely small compass, is equally efficient, and much cheaper than any of the others we have seen.

TRAVELLING HOSPITALS FOR CHOLERA.

AMONG the measures proposed in Paris for managing the cholera when it reaches that city, is the establishment of *ambulances* in each quarter. There will be a body of physicians, apothecaries, and nurses, ready to give the speediest succour. "It will be so ordered," says the proposer, "that the disease, the doctor, and the remedy, may enter together, or close on each other's heels;" "and that *death* also may probably be of the party"—adds one of the wicked wits.

"BURKING."

WE have just time and space to mention that Bishop and his accomplices, who were this day (Friday) tried at the Old Bailey, for the murder of the Italian boy, have been found *Guilty*.

NOTICES.

WE are greatly indebted to our correspondents (more numerous than we have space individually to answer) for their communications. That as little delay as possible might take place, we have this week given an extra sheet. Some on questions of a less temporary nature are postponed till the next and following Numbers.

BOOKS RECEIVED FOR REVIEW.

Researches to establish the truth of the Linnæan Doctrine of Animate Contagions. By Adam Neale, M.D.

An Inaugural Dissertation on the Congenital Malformations of the Heart. By John Paget, M.D.

A Memorial presented to the Medical and Surgical Officers of the Worcester, Salop, Birmingham, Gloucester, and Hereford Infirmaries, on the Abuses existing in the Public Hospitals; with an Appendix, containing the Answers received from them.

A Critical and Experimental Essay on the Circulation of the Blood. By Marshall Hall, M.D.

Lectures on Anatomy. Vol. III. By B. B. Cooper, F.R.S.

Practical Remarks on the Nature and Treatment of Fractures of the Trunk and Extremities. By Joseph Amesbury.

The Principles of Surgery. By James Syme, F.R.S.E.

ERRATA.

In our last No. p. 267, last line but one, for "color," read "calor," and in p. 269, for "3ij." read "ʒij."

LECTURES

ON

THE THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

PART I.—LECTURE X.

I MENTIONED, gentlemen, in the last lecture, that I did not think the circumstance of the coagulation of healthy blood—not to say the circumstance of any of the diseased appearances—was at all explained; that I was not satisfied with any of the explanations which had hitherto been given. I forgot to mention, that I think I put together all the arguments—every thing that I can say to you here—in fact, every thing I know upon the subject, in one of the notes on the blood, in Blumenbach's Physiology. I feel a little delicacy in referring to a book of my own, but I trust you will excuse me if I should have occasion to do so in the course of these lectures.

I do not know that we have any sufficient reason given either, for the cause of the buffiness of inflamed blood. Perhaps it is owing to the thinness of the fibrin. It is said that the fibrin is thinner in inflamed than in healthy blood; and if this be the case, we may imagine that the red particles will subside more easily than if the fibrin were of its healthy consistence.

I spoke, at the end of the lecture, of what are called the various terminations of inflammation. I considered resolution and effusion, and was particularly considering, at the close of the lecture, suppuration, that effect of inflammation in which a new fluid is produced, called *pus*. I was stating, that when this new fluid is collected together within a cup, or at least when it is collected together and not diffused, an abscess is

said to exist. I mentioned that the structure of an abscess, in general, is this—lymph is thrown out, pus is formed in the middle of it, and the cellular membrane immediately exterior to the lymph is condensed, becomes firmer than the rest of the cellular membrane, so as to back the cup of fibrin. When the pus is fully collected and ready for exit, the lymph is gradually absorbed in one part, and that part is nearest to the exterior of the body, or nearest to some natural outlet, so that the pus can escape by the surface, or by the intestines, the trachea, the bronchiæ, the stomach, the bladder, or any canal which runs to the surface. If there be any danger of mischief arising from the circumstance of the walls of the abscess becoming thin, and letting out the pus into a cavity, or part of the body where serious consequences would result—as, for instance, into the peritoneum—then a great deal of additional lymph is frequently thrown out, glueing the various parts together, in order to prevent as much as possible the liability of the escape of the pus in an improper direction. Thus you see that nature usually thins the walls of the abscess at that point which is most eligible for the escape of the pus, and thickens them where it would be dangerous for the pus to escape. I stated that nothing could be more beautiful in nature than this provision.

Pointing.

The absorption at this point, wherever it may be, goes on. If it be near the surface we see the chief swelling at one particular part, and the collection is said to *point*. At length a minute opening is formed, and the matter escapes. When the latter occurrence takes place, and the cavity is thus opened, minute red granules are seen within, highly vascular, soft, covered with pus, and which, in fact, secrete the pus. Sometimes the opening at which the matter escapes, although small at first, enlarges, absorption takes place to a great extent, ulceration runs on to a considerable distance, and perhaps lays bare the cavity very much.

Granulation.

Those red granules which secrete the pus grow larger and larger, and advance forwards till the cavity is filled up. This process is called *granulation*. When the cavity is entirely filled up, portions of skin form upon its surface, and portions of the surrounding skin prolongate into them, so that you have a double source of new skin. Fresh skin appears in insulated points, and the healthy skin around shoots prolongations into it. In this way the surface of the granulations becomes covered with skin, and is healed.

But from the loss of cellular substance which takes place in the formation of the abscess—for the cellular membrane is more or less destroyed; and from the contraction of the new parts—for these granules, which were very vascular at first, become less and less so; from the loss of the cellular membrane, and the contraction of the new parts, when all is healed, we see a depression. If it be a very minute abscess, such as is only called a *pock*, as in small-pox—then you have merely a little depression, a pit; but if it be a more extensive formation of matter that has taken place, then you have *scars*. They are exactly the same thing, only on a different scale. The contraction of the new parts, and the loss of the cellular membrane, are sometimes such that the joints cannot be extended, and the arm becomes bent to the body, or the fingers bent down to the hand.

Diffused Suppuration.

It is said that the pus is sometimes collected in this way in an abscess, without any lining of lymph; but when the latter is absent the pus is almost always diffused. You frequently have pus formed in the cellular membrane in a diffused manner, so that it will run to a great extent and do very serious mischief, producing, wherever it spreads, new inflammation and the most frightful devastation. This is observed in that form of erysipelas styled *erysipelas phlegmonoides*. Where suppuration takes place in the cellular membrane, uncontrolled by a cup of lymph, it often runs on extensively, and sometimes a whole arm, or a whole thigh, is covered by a sheet of matter in this way.

You will, however, sometimes have a formation of pus, and an absorption of the skin and cellular membrane, without any collection of matter. This is seen every day in the case of the throat, and sometimes upon the skin itself, but more frequently upon a mucous membrane. If a mucous membrane be attacked by a slight inflammation, the epithelium may be absorbed, together with a small portion of the mucous membrane—in fact, you may have an ulcer, and that ulcer will secrete pus without there being a collection of matter underneath. In an abscess the matter is formed in the cellular membrane, or a solid structure, and tends out-

wards; but frequently in a mucous membrane—nothing is more common than to see this in the throat—the process goes on inwards. The surface, which is a little inflamed, becomes abraded, matter is formed upon it, and in that way you have an ulcer without the previous existence of an abscess. If the part heal, it is afterwards filled up in the same way as if the matter had been collected in a cup in the cellular membrane.

Qualities of Pus.

Pus, if healthy, is an opaque fluid, yellow or white, homogeneous, short, and creamy; so that, if you take a drop between your fingers and separate them, it breaks; the drop divides into two—does not hang in strings. It is bland generally to the taste, and without smell;—some say it is rather *marckish*—but one never thinks of tasting it, except in the case of a gum-boil, or other suppuration in one's own mouth. If it be perfectly healthy it is inodorous and bland, or at the utmost there is only a *marckish* taste. It is said to be neither acid nor alkaline, although, by exposure to the atmosphere, it turns sour. It is also insoluble in water. It contains globules; and hence it is distinguished from pure mucus by being placed between two bits of glass, and then looked through at the sun. From the existence of the globules you have an iridescent appearance, the colours of the rainbow. This is not the case with mucus; for mucus contains no globules. Mucus, again, is not short, like pus. If you take a portion of mucus between the finger and thumb, and separate them, you find that it drags out into threads; it does not break off short, like pus. I believe it is known by those who have had much to do with gonorrhœa, that, when the disease is violent, the secretion from the mucous membrane is purulent—it regularly breaks off between the fingers; whereas, when the disease declines, and pure mucus is again secreted, a person has a full conviction that he is getting better, by finding that the discharge will drag out between the finger and the thumb. When, however, pus is first secreted, it is said not to be globular, and that these globules do not appear in it till it has been poured forth from the vessels for fifteen minutes.

Persons have endeavoured to discover the difference between pus and mucus by chemical tests. John Hunter says that he found pus easily coagulate by a solution of muriate of ammonia, but that mucus would not. Dr. Darwin, jun., says that a solution of caustic potass does not dissolve pus, but makes it a viscid semi-fluid substance, stringy, like mucus, not dissolvable in water, but resembling the diseased mucus of the bladder. When that viscus is in a state of chronic inflammation—when the mucous membrane is in a state of cystorrhœa, and there is a great

discharge of mucus from the surface—its mucus is very ropy, and may be dragged out to a great length; and this is the appearance which pus exhibits if it be mixed with a solution of caustic potass. Dr. Darwin, jun., also says that the same effect is produced by adding to the pus sulphuric acid; whereas, if you add these things to healthy mucus, small flakes are produced, and not a stringy semipellucid substance. On the other hand, two modern French writers, Andral and Baumes, deny this distinction. Then you find another chemist say (Grasmeyer) that if pus be triturated with an equal quantity of water and then this combined fluid is mixed with an equal quantity of carbonate of potass, a jelly is produced in a few hours; but that this is not the case with mucus. Pus in general sinks in water, but mucus generally does not; and if pus be diffused in water, the water becomes uniformly white.

However, as to all these distinctions, the fact is, that pus and mucus run into each other. Mucus may be diseased, so as to be something like pus—puriform; and they will run into each other by insensible degrees. In disease of the lungs, the distinction between pus and mucus has been thought most important, as tending to shew whether ulceration exists; but here the two secretions are continually mixed together. When there is an abscess of the lungs, or a number of abscesses, and matter is discharged from them, you will have at the same time a quantity of mucus secreted from the bronchial tubes, so that the pus and the mucus are expectorated together; and in proportion as the former surpasses in quantity the latter, or the latter exceeds the quantity of the former, you have the character of the one or the other. If the quantity of mucus be very considerable, the pus may be borne up by it in water—not allowed to sink. Besides this, there may be an abscess in the lungs, and there may be also an excavation, and this not secreting pus, but really mucus. The lining membrane of the cavity in the lungs, at least if fresh ulceration have not taken place, may secrete merely mucus. Again, every mucous membrane which is inflamed may produce absolute pus; so that you may see pus discharged from the lungs when there is no ulceration at all. On the other hand, there may be an ulceration of the lungs, but the lining membrane of the abscess may have become of such a mucous character that it secretes really mucus, and nothing else. In addition to this, you may have mucus from an abscess in the lungs and pus from the bronchial tubes, in consequence of these being in a state of irritation, combined together in various proportions; so that the distinction between the two is not of the importance which was once imagined.

With regard to the constitution of the pus,

Schwilgué, who is one of the last that has analyzed it, says that it consists of albumen—of extractive matter, fatty matter, soda, muriate of soda, phosphate of lime, and some other salts. When pus is scrofulous, it is said to have more soda and muriate of soda than healthy pus. Pus was once imagined to consist of the dissolved solids; seeing that a cavity existed, it was imagined that the solids were melted down and turned into pus. But then you frequently have pus, as I just now stated, when there is no ulceration at all, and the formation of pus is not in proportion to the loss of the solids. You may have, from a small abscess, an immense secretion of pus, if by chance the abscess do not heal, and yet it does not extend. The truth is, the pus is a new secretion. Whether globules are formed in it—whether it is perfect or not, immediately—whether fifteen minutes are required to produce the globules and fully form the pus—is of no consideration; the fluid which constitutes the pus is, to all intents and purposes, a secretion. Yet I believe pus will dissolve dead solids; although it is not dissolved solids, yet it will itself dissolve them, making a solution of them if they be dead. John Hunter found dead flesh dissolve very readily in pus. He put an equal quantity of dead flesh into pus, into jelly, and into water; and he found that portion put into pus dissolve very readily, while the portions put into jelly and water did not. Hence it would appear that pus is useful in dissolving the solids when they die; and the cellular membrane continually dies in phlegmon. When an abscess is formed, the pus, no doubt, dissolves a portion of the cellular membrane, but still it does not dissolve it all; for when you open an abscess, you continually see portions of dead cellular membrane, which are called by the common people the *core*, escape.

Healthy pus is called by the old writers *laudable*. I recollect, when a student, hearing good pus, instead of being termed healthy pus, commonly called *laudable* pus—*praiseworthy* pus. Healthy pus should abound with globules. I may mention that one writer (M. Gendrin) says that these globules differ from the globules of the blood only in being larger, and of an opaque yellow colour. Some say that the term globule is improper—that these particles are not exactly globular, but irregular in size and shape—but still all agree that there are certain particles in the pus, as there are in the blood.

Healthy pus should abound with globules; but if they be deficient, and it watery, then we have what is called *ichorous* pus; but there may be other differences in pus besides a deficiency of globules. When pus is thin, like water, it is called *ichorous*; if it be thin and bloody, then it is called *sanious*; and it is called *scrofulous* if there

be little curds in it, which very possibly are shreds of lymph. Pus sometimes very much resembles mucus, does not abound sufficiently in globules, and is glairy or muciform, and will hang out in little slight strings. When mucus, however, becomes something like pus, we call it puriform. Although healthy pus is inodorous, and said to be only mawkish to the taste, it frequently becomes fetid. This particularly occurs if a bone be diseased; but in suppuration of the tonsils it is not uncommon for the pus which escapes, or is let out by a lancet, to be most horridly fetid; generally, however, when pus comes from a bone, or the immediate neighbourhood of a bone, it assumes this fetid character.

Early Formation of Pus.

I mentioned in the last lecture in how short a time lymph and fibrin were seen effused in a serous membrane; and pus also has been seen to form in a few hours: it has been seen produced in a mucous membrane in a few hours after inflammation has been set up; and when an abscess has been produced, matter has been formed in so short a time as from twelve to eighteen hours from the commencement of the inflammation.

Proud Flesh.

I should have mentioned, when speaking of granulations, that the smaller they are the better; for if they be large they are generally spongy, and the common people then denominate them *proud flesh*.

Mortification.

The next termination of which I will speak is *mortification*. This is shewn by the part becoming of a darker red than before. When a part is about to mortify, it grows of a dingy red; from red it becomes purple, and then black; and when it is once dead, from the decomposition of the matter, it changes to a green colour and various other hues. The pain ceases, the part becomes cold, and, if it be the surface, we often see vesicles, which, although they are frequently filled with a pale fluid, yet are more frequently filled with a bloody serum. If it be the skin which is mortified, it becomes variegated, and perhaps the part crackles, too, under the finger. From the extravasation of air the swelling increases; and the part has often a doughy feel. These are the local symptoms, but general symptoms take place. There is extreme prostration of strength and extreme restlessness. The face becomes ghastly; the pulse becomes rapid and exceedingly weak, perhaps intermitting and irregular. There is a general fall of the temperature of the body, and a cold clammy sweat takes place. The tongue becomes brown or black, the manner becomes exceedingly quick, and frequently a little delirium takes place. The cessation of the

local and all the violent general symptoms will take place just before death from inflammation, when that inflammation does not cause mortification, or any other local change—although, when mortification occurs to any extent, you will have the very same thing, that is to say, the cessation of pain, the ghastly countenance, the rapid, feeble pulse, the extreme sense of debility, restlessness, and at last death, without any mortification—without any other local change whatever. I believe I mentioned before, that frequently from the symptoms of enteritis, you would imagine that mortification of the intestines had taken place, but on opening the body you may find no mortification, nothing but intense inflammation.

When the parts inflamed become of a purple colour, and cold, and fall into incipient mortification, restoration is not impossible: parts will recover that have become purple; and lost a portion of their temperature. Even parts which have been congealed will recover by good management; but this, I believe, takes place in man and the other warm-blooded, more than in cold-blooded animals; and Professor Thomson, of Edinburgh, says, if a *whole* limb is frozen it is never restored. A still higher degree of mortification is called *gangrene*; and the complete death of a part—when it is dead, gone irrecoverably—is termed *sphacelus*. In the latter case, the part is cold, senseless, black; and putrefaction follows. There are three degrees, therefore, of mortification:—the one where the parts are merely purple and cold; a second where things are more advanced, but the part is not absolutely dead; and the third, in which the part is really dead,—mortification being the generic term for all the three stages. When a part is dead, and putrefaction is begun, the progress of the putrefaction depends very much upon external circumstances. The warmer the weather, of course the more readily will putrefaction take place.

Separation.

If the part, which is in a state of sphacelus, is not important to life, it may be separated by nature from the body. The process of nature here is exceedingly wonderful. The large vessels, which go to the part, become plugged up—a coagulum of blood forms in them, or adhesive fibrin is poured out from the inner surface, so that in one way or other the progress of the blood is arrested; the consequence of which is, that it coagulates to some extent above the plug, and the plug thereby becomes increased. Dr. Thompson, of Edinburgh, says, that a coagulum never extends higher than the first communicating branch, and that one would suppose. The blood coagulates behind the

plug, nearest to the heart, and you cannot, therefore, expect a plug to extend beyond the first communicating branch. He says that sometimes he has seen a vessel entirely connected together, completely obstructed, without the formation of any plug at all, the whole obstruction being produced by an effusion of lymph, lymph which has become organized, and formed an internal adhesion. Nay, he says that sometimes he has seen an artery completely obstructed without any lymph, without any plug, but simply from its becoming closely contracted, so contracted that it would not admit a bristle. The contraction has formed as complete an obstruction to the blood as the existence of a coagulum, or a quantity of fibrin would have done. He says that he has noticed the same circumstance in an amputation where no ligature had been employed. The vessels have become so contracted as not to admit of the introduction of a bristle, and have thus prevented all hæmorrhage. In whatever way it is done, whether by a coagulum of blood, whether by a plug of lymph forming an adhesion, or by the mere contraction of the vessels, or by any two of these, such is the fact, that nature generally succeeds in preventing hæmorrhage from a mortified part, by obstructing the course of the blood in the larger vessels leading to it.

Then the process of separation is accomplished in this manner: a red line appears at the boundary of the healthy part which is nearest to that which is dead. This red line, of course, is a line of inflammation, and in it ulceration takes place, which goes down in the healthy part lower and lower, till a complete separation takes place; and in this way a whole limb is sometimes separated from the body.

Necrosis.

Of course I have been speaking of soft parts; but if a long bone die, which is a very common thing, without any death, or any especial disease, of the surrounding parts, a new bone is formed around it. The process of nature, therefore, is quite different here from that which is employed to separate a dead soft part. In this case a new bone is formed under the periosteum, around the dead portion; and in this way what is exterior to the new bone, namely, the periosteum, the ligaments, and the cartilages, all become attached to it. When the old bone within the new one is detached, completely loosened, then an opening is formed in the new bone, ulceration takes place in it at one spot, granulations occur on the inner surface; and these granulations push the old bone through the ulcerated opening in the new one—at least they tend to do so. The aid of a surgeon is frequently of use in assisting to draw out the old bone, and enlarge the openings in the new; but this is the process adopted by nature when a bone dies.

[The learned professor here exhibited a beautiful specimen illustrative of these remarks.]

This process is called *necrosis*; and the old bone within will frequently rattle like the kernel of a dry nut. The old bone is called *sequestra*.

Exfoliation.

If, however, it be not a long bone which is dead, but merely a plate, or a flat bone, this is separated by ulceration. Granulations form under the old bone and push it off. This process is designated *exfoliation*, because the bone comes off like a leaf.

Terminations.

These are the "terminations," as they are called, of inflammation; but I should rather say, they were the *effects* of inflammation than terminations, because inflammation does not necessarily terminate when they occur. Inflammation frequently goes on after these effects take place, and therefore we ought to say, strictly speaking, that these are the effects of inflammation, or circumstances that occur from inflammation.

You will find that authors enumerate among the terminations of inflammation, *scirrhus*; but if by that they mean the *scirrhus* which afterwards becomes cancer, they are certainly wrong, because *scirrhus* will occur without marks of inflammation: a part without these will gradually become cancerous—seems a specific disease. If, however, by *scirrhus* these writers mean true *scirrhus*, mere induration, then they may be right, because one of the effects of inflammation is to harden. When a part has been inflamed for a length of time, it frequently becomes indurated, so that *scirrhus*, in that sense, may be said to be the effect of inflammation, but not a termination of it, because the inflammation will go on, and the part become more and more indurated. Induration, however, is only one of such effects of inflammation which they ought to enumerate, for it has as great a tendency to cause parts to become softened as hardened. Induration is rather the effect of chronic inflammation, while acute rather produces softening.

Duration of Inflammation.

Having spoken of the effects of inflammation, I now proceed to consider its duration, and this is very various, much depending upon its intensity. If an inflammation be exceedingly violent, it cannot last long; but if that be not the case, it may last a great length of time. Inflammation may exist for only a very few hours, and may certainly destroy life in the course of a day: it is sometimes so rapid that a person shall be well in the afternoon, and die from it before the next morning is much advanced. I recollect myself seeing last winter a case of

pericarditis, which occurred suddenly in the evening, about seven o'clock, from a lady having exposed herself to cold by walking about the house half-undressed, and she was dead before eight the next morning. Inflammation may be so acute as to destroy life in a few hours without any mortification, but simply from its own intensity. Inflammation may be even almost momentary, but that will depend upon the use you choose to make of words. Certainly a child is sometimes seized with a violent rush of blood to the head, its eyes will become red, —in adults the same thing will happen—its face flushed, its head distracted with violent pain, it screams, and death ensues in the space of one or two minutes. After death a great quantity of blood will be found within the cranium, and externally to it. If this state be inflammatory, it certainly proves that inflammation may be almost momentary, and that it will destroy life in this sudden manner.

But inflammation, if it be not violent, may last for many months, and even years; for if it remit, it may be tolerably violent often, and yet continue for a very long time, its severity not remaining the same during the whole of the period. If it once degenerate into the chronic form, it may last indefinitely, and when it does so, it generally induces various changes of structure, which I will hereafter mention. When a part has been once inflamed, the redness will occasionally remain some years without any pain or any heat. You may see this frequently after burns, and after cutaneous diseases. A portion of a scar will remain exceedingly red, the vessels would appear to be in a state of passive dilatation; there is no pain, no heat, no tenderness, but extreme redness; and this, after it has existed a year or two, or perhaps longer, will sometimes decline; the vessels will gradually at last recover their natural tone. After ulceration the skin will frequently remain of a red colour, perhaps of a very dingy red, and almost of brown colour. In the case of a person who has had a sore leg, you will see that the portions corresponding with the spots of ulceration are frequently very red, brown, variously discoloured, or perhaps nearly black.

Such, gentlemen, are the usual phenomena of inflammation, such are the chief symptoms, such are the general effects or terminations, and such is its course. The next point which I will consider is the variety in all these symptoms, and the variety in its course, occasioned by the nature of the structure which it attacks. As, however, this is a new subject, I had better defer its consideration until the commencement of the next lecture.

CLINICAL LECTURE,

Delivered at St. Bartholomew's Hospital, Nov. 9,

By H. EARLE, F.R.S.

Tracheotomy; especially as applicable in cases where Children have drunk boiling water.

EDWARD ELMORE, æt. 2½, was admitted into Queen's ward on the night of the 4th of November.

Six hours before, he had drank some water from the spout of a tea-kettle, which had been recently boiling. Upon admission, the respiration was very laboured, and accompanied by a sound evidently arising from some obstruction in the larynx. She seemed in pain, but could speak with tolerable plainness, and had swallowed fluids recently. Some leeches were directly applied, and seemed to relieve the child much. After a while, however, she again became worse; the leeches were repeated, and an aperient powder ordered.

About 1 o'clock next day, (18 hours after the occurrence of the accident) Mr. Earle saw the child. At this time, the air was evidently propelled with great difficulty through the larynx, and the chest was but incompletely filled at each inspiration, although, on applying the ear, some air was heard to enter, accompanied by a crepitating sound. The child lay back motionless upon the bed, although she was perfectly conscious, spoke to her mother once, and coughed now and then. The lips were livid, and her countenance anxious.

It occurred to Mr. Earle, that in such cases as the present, the operation of tracheotomy might be of service; and although the little sufferer, in this instance, was too far gone for any sanguine hope of relieving her being entertained, yet, as the only chance of saving her life, he proposed it. Mr. Lawrence agreed that the case perfectly justified the performance of the operation.

In the attempt to remove a portion of one of the rings of the trachea, one of the thyroid veins was wounded. As this bled rather freely, the operation was deferred for about half an hour. Eventually, an opening was made of sufficient size to permit the introduction of a portion of a large-sized gum catheter, through which the air freely passed.

Shortly afterwards, the child opened her eyes wide, her countenance brightened up, and she looked much revived, as all present remarked. This improvement was not, however, progressive; the child never rallied to any extent, and died without a struggle in the course of the afternoon, having lived about 24 hours after swallowing the water.

After the tube was introduced, constant attention was required to remove the mucus, which every now and then blocked it up, producing, by its obstructing the passage of air through the tube, all the former difficulty

of breathing, which was immediately relieved by removing this mucus.

Upon examination some hours afterwards, the mischief was found to be chiefly confined to the glottis, and parts immediately around it. Considerable thickening of the arytenoid cartilages; a shrivelled, corrugated state of the epiglottis, which was also superficially ulcerated, its edges being at the same time in a sloughy state.

Some inflammatory appearances, likewise, were found along the trachea and bronchi, which, however, did not seem to arise from continuity of surface, as the superior portion of the tube, where the opening had been made, was not so much inflamed as the lower.

The lungs were loaded with serum and blood; and, in some considerable portions, were so much consolidated, as must have prevented the entrance of air at these points.

Mr. Earle, in his clinical lecture, made the following remarks upon this case:—

He observed, that cases of this description were not very uncommon in their occurrence among the children of the poor. Some fatal cases have been published by Mr. Stanley and Dr. Marshall Hall, in the *Medico-Chirurgical Transactions*. It occurred to Mr. Earle, some time back, that it would be proper to perform tracheotomy in such cases, but this was the first case that had occurred in his practice. He was not aware until after the death of this child that the same idea had suggested itself to, and had been acted upon, by Dr. Hall, at Nottingham, who published a paper detailing some cases. In only one of these an operation was performed. This was done twelve hours after the accident had occurred, and the child lived thirty-six hours; whereas, in all the other cases he relates, death took place much more rapidly.

The epiglottis and surrounding parts are, by such accidents, injured in such a degree as to become unfit to perform their functions; added to which there is much spasmodic contraction in the rima glottidis, similar to what occurs in acute laryngitis, in which disease tracheotomy affords the best chance of recovery.

In a part of such vital importance as the larynx, it is very doubtful whether we can trust to mere antiphlogistic measures, although employed at an early period, and with activity, whether such affection be dependent on any injury, or be an idiopathic inflammatory attack. It is not merely the affection of the organ itself that is of importance, but through it other important parts suffer. From the injury done to this one portion, the whole of the respiratory apparatus becomes deranged. Even should we succeed in arresting the inflammatory action, yet we must recollect that inflammation is a process, and that the local actions already commenced may destroy a patient, although

the general inflammatory state may be arrested.

From a mere consideration of post-mortem appearances, we do not see the full extent of the affection. This part is endowed with the highest degree of sensibility and irritability, consequently inflammation in its neighbourhood produces the most violent spasmodic action.

The extreme sensibility of the larynx, as contrasted with the minor degree which exists in the trachea, is well demonstrated by what occurs upon the introduction of a foreign body. A foreign body, upon being introduced into the larynx, excites the greatest possible irritation; but on descending into the trachea, so little does it cause, that a practitioner, if not aware of this circumstance, might doubt the presence of such body until the patient by coughing, or other violent exertion, forces it up to the larynx, and thus reproduces the dreadful spasmodic irritation. This high degree of sensibility is no doubt provided for the wisest purposes, namely, to prevent the ingress of any foreign body during the act of deglutition.

In consequence of its obstructing the free egress and ingress of air, an inflammatory affection of the larynx exerts a rapidly-destructive influence upon the lungs; consequently no operations, unless performed prior to the occurrence of such changes, can be of any avail.

In the present case the lungs were loaded with serum, and in a great measure consolidated; the blood sent to them could be only half oxygenated, and in such a state must exert a deleterious effect upon the sensorium and nervous system. This causes a diminution of nervous energy, which again will react upon the lungs.

Dr. Philip relates, in his experiments upon animals, that where he has cut off the supply of nervous influence the lungs have become speedily loaded and hepatized. These experiments in some measure explain the very rapid changes effected in the lungs in acute laryngitis, and cases like the present, where severe injury has been inflicted on the glottis and larynx. The operation in the present case could scarcely, after so long a delay, have been expected to succeed; and, therefore, its want of success should not militate against the future performance of it in other cases at an earlier period.

There are two operations by which the object may be effected:—1. The removal of a portion of one or more of the rings of the trachea. 2. The forming an aperture between the thyroid and cricoid cartilages.

The first of these is difficult of performance in a young child, or a deep-necked female, and dangerous from the great number of veins which ramify about this part, the wounding of one of which arrested the operation in the present case. The mobility of

the larynx is also very great indeed, rendering it difficult to fix it for a short time, in order to remove a portion of it; and, from the nature of its texture, the knife will slip over it rather than penetrate it, unless it be held firm. This object may in some degree be effected by thrusting a tenaculum into it, and thus in some measure restraining its motions—which expedient was resorted to in the present case. Another danger arises from the irregular distribution of the carotid arteries, which sometimes occurs.

The other mode of operating is far more easy, and in the present case would have sufficed, as the inflammatory action had not proceeded far down the larynx, although it was impossible to be certain of this beforehand. But in acute laryngitis the first of these operations must be performed, as the whole larynx often participates in the inflammation, and therefore the farther from the seat of disease the operation be performed, the more chance of success. Mr. Earle referred to the case of a patient of Dr. Latham's, in Mary's ward, upon whom he performed tracheotomy last summer, when she was upon the eve of death, for acute laryngitis. In this case he could not but attribute the happy issue of the case to his having performed the operation at a point sufficiently remote from the disease. There are some points of difference in acute laryngitis, and the affection resulting from local injury to this part. In the former the greatest difficulty attends an attempt at deglutition, and there is also great tenderness evinced upon pressure being made in the region of the larynx.

In a subsequent lecture Mr. Earle observed that at the close of his last lecture a gentleman related a case to him, in which the operation had been successful, which had occurred at the Salisbury Infirmary. He had since furnished him with the details of the case, which Mr. Earle read to the class.

The child was sixteen months old, and the operation was performed two hours after the accident had occurred, and succeeded perfectly. This case, of course, proves in the strongest manner the propriety and utility of performing the operation before the disorganizing process had commenced in the lungs. In the progress of both this case, and that before alluded to, as detailed by Dr. Hall, portions of the food were occasionally observed to pass out at the external wound. Now as the action of the boiling water is so immediately upon the epiglottis, corrugating it, and unfitting it from closing perfectly the aperture into the larynx, this circumstance would seem to go far in determining the true use of this part. Magendie considers the epiglottis as an organ of the voice, and not of deglutition. In experiments upon animals, or in accidents in battle, it has been removed with the effect of impairing the

voice much by its loss, yet such subjects have been enabled to swallow after a time.

When we consider the admirable adaptation of the epiglottis to the part it covers, we cannot but coincide with the old opinion that it is (at least in part) an organ of deglutition; and in reference to the deductions we draw from experiments and accidents, we should always bear in mind the very great compensating and reparative efforts of nature upon these and all similar occasions. During sleep, when all parts are in a more or less torpid state, if it were not for some such contrivance, the saliva so copiously secreted in catarrh and in salivation, would pass into the larynx, exciting distressing cough. There is a man in Pitcairn's ward, of the name of Burgess, who has now come in with a phagadenic ulcer of the leg, who was a patient in 1828. He then had an extensive sloughing ulcer of his throat, which extended to, and destroyed the epiglottis. For a long time after this occurrence, whenever he took food or drink, he had a most distressing fear of suffocation. Now, however, he has recovered in some measure his voice, and has lost all the dread of swallowing he once possessed. This man entertained the fear of suffocation as long as the parts remained in their unprotected state, but has since entirely lost it.

Mr. Earle next alluded to the following case, which, from the symptoms, was supposed to be one of chronic laryngitis.

Godfrey Wolmer, æt. 60, gold refiner, admitted into Powell's ward, November 4th. Countenance anxious, sallow, and aged; respiration very difficult, and accompanied by a wheezing sound heard at a considerable distance. The difficulty seems, however, to be entirely confined to the larynx. Occasionally it is aggravated by severe paroxysms, which oblige him, if he be lying down, to start up, from fear of being suffocated. All exertion increases his distress much. Occasional cough, accompanied by the expectoration of a viscid mucus, and often purulent matter. This cough, however, does not seem to affect his chest, but merely acts, as he says, by clearing his throat of the mucus, which being expelled with a very peculiar noise, affords him great temporary ease. Voice husky, and sometimes almost inaudible. He says his deglutition is very arduous, but those about him state that it is not very difficult. He, however, complains of his food lodging for a time at the upper part of the throat. Very little tenderness is excited by pressing the larynx. Dr. Latham examined his chest. Percussion was every where good. The respiration was scarcely audible, owing to the small quantity of air admitted to the lungs, but no unnatural sound was detected. The old man, on admission, was in an enfeebled state, and seemed only half alive.

The history he gave of his complaint was vague; he referred it to no distinct origin, and even gave different accounts as to its duration. It seems, however, it certainly had existed nine months, and had become much worse during the last three. He has been long out of employ, and living in a very indifferent manner; and, indeed, latterly the severity of his sufferings would have incapacitated him from undertaking any, which required exertion.

Active counter-irritation was applied to the throat, but he continued going on much the same. The house-surgeon was several times called to him when in paroxysms of dyspnoea, which seemed to threaten his life. Opium given internally, and inhaled, relieved him much of this spasmodic irritation.

It was thought that this man laboured under chronic laryngitis; and although, from the long duration of the disease, irreparable destructive changes in the part had probably occurred, yet, as perfect rest of the parts affected afforded the *only* chance of their reparation, and as the man's life, during these paroxysms, was in infinite danger, Mr. Earle considered it a proper case for the performance of tracheotomy; as a means, at all events, of prolonging the patient's life, and in no way adding to his danger.

In this view of the case, Dr. Latham and Mr. Lawrence coincided, and it was agreed to perform the operation the next day.

On the evening before, however, he was seized with another paroxysm; the house-surgeon was sent for, and performed the operation: it was too late—he died directly after. Upon examining his body, the tunica arachnoides was found very much thickened indeed, and beneath it was most copious effusion. The ventricles of the brain were also distended by fluid. The epiglottis was nearly natural in its texture and appearance, slightly thickened, and turned to one side by a portion of the tumor about to be described; each arytenoid cartilage was to be converted into a large mass of cartilaginous hardness and irregular form, nearly closing the rima glottidis. The œsophagus, at its origin, was much contracted, and becoming converted into the same indurated substance as the arytenoid cartilages. The lungs were loaded with a sanguineo-mucous fluid, the lower lobes being much condensed.

Mr. Earle observed, that although, from the inveterate nature of the affection, cure would have been out of the question, yet, had the operation been performed sooner, this man's life might have been prolonged.

OBSERVATIONS ON THE CHOLERA MORBUS OF INDIA.

By J. SPENCE,

Assistant Surgeon, 52d Regiment.

THE mystery which has hitherto enveloped the nature of cholera morbus, and the fatality with which it has almost universally been attended, are circumstances of themselves sufficiently urgent imperatively to call upon individuals having experience in the disease to make public the result of their observations; which, being done with candour, cannot fail to be interesting.

Formerly, spasmodic cholera was a disease which professional men, not destined for service in India, were somewhat careless of, looking upon it as one which they were never more than nominally to know. Now, however, since it has passed the boundary of the tropics—since it has committed such devastation on the Continent of Europe—all are eager to gain information regarding it; the attention of all classes is directed towards it; in fact, cholera is the lion of the day; and therefore I hesitate not to offer to the public some brief remarks, which, having been collected at the bed-side of a very great number of patients, may perhaps be acceptable.

The cause of cholera morbus is necessarily a most important matter, involving, as it does, not only our vital, but mercantile interests, and therefore should not too hastily be dismissed from our consideration. But, to arrive at a correct conclusion, the profession ought to enter upon the investigation perfectly unbiassed by any notions previously entertained, regarding its contagious or non-contagious qualities; with reference to which I cannot but lament that the opinions I have adopted are opposed to those acted upon by the highly-distinguished individuals appointed by the government for the elucidation of this subject. In forming these opinions, however, I have been actuated only by the desire of attaining the truth, and believe the conclusions arrived at to be the fair inference from the facts presented.

I have seen very many cases of cholera morbus in the Presidency of Bombay, and a few at Colombo, in Ceylon. Once only when it occurred as an epidemic. At other times the cases were separate

from each other by a greater or less interval of time; which latter fact is one of much weight in the argument, for if it can be proved that a genuine case of cholera can occur, and the patient be treated and dies while in the midst of persons, none of whom become infected, I think it certainly a proof that the disease could have no power of propagating itself. To bear me out in the fact that such instances are very frequently met with, I would call for the testimony of every practitioner who has been even six months in India. One instance might occur, and the individuals in the same ward, or in attendance upon the sick person, might not be predisposed; but is it likely that it should be observed a hundred times with the same result?—and I feel confident that I could, with the assistance of my friends, adduce a greater number than I have mentioned. When the disease, then, attacks individuals thus sporadically (say one in a month), I think I may safely assume that it neither had its origin in contagion nor did it manifest the property of a disease of that class. I then, from this, am led to inquire whether there be any difference perceptible in the symptoms, or signs after death, between a case of cholera under the above circumstances and one occurring when the disease is epidemic? To this I can most confidently answer in the negative; admitting them both to have the symptom which forms the grand diagnostic of the spasmodic Indian cholera—namely, the evacuations per anum resembling rice water: this being present, I repeat that there is no distinction whatever. I have seen cases, and, so far as I remember, all those which occurred whilst I was at Ceylon, were of the same character, in which there was violent vomiting and purging, with cramps and great exhaustion; but the stools were not white, and evidently contained bilious matter; the patients all recovered. But this is a very different form of disease to that which I shall presently describe.

It often happens that detachments marching in India, on arriving at certain encampments, become attacked with cholera; and it is then the universal custom immediately to strike the camp, and the disease usually disappears. Fortunately, the persons in authority, never thinking of contagion, remove the sick with them, if possible. Wretched,

indeed, would be the situation of an infected person, did those around believe him capable of contaminating them: to propagate such a doctrine would cause the helpless sufferer to die without attendance. One gentleman, with whom I am acquainted, arrived in Bombay harbour, from New South Wales, with a detachment of recruits; they immediately proceeded on the march to Poonah; but on the second day, having arrived at an encampment situated at the foot of the mountains, or ghauts, as they are called, cholera broke out, and, in the course of a few hours, he lost a number of men, and became affected himself, having, with the rest, been an hour previously in excellent health. As soon as possible they proceeded up the ghauts, and it was my friend's good luck to recover, although, during the march (being moved in a palanquin), his dissolution was greatly feared. On arriving at Kandallap, a distance of about five miles from Campoolie, but at least 3000 feet above its level, the disease disappeared. Between the native inhabitants of these two villages there exists the most unlimited communication; moreover, there are constantly whole hordes of native travellers passing through them, along the road between Panwell and Poonah. Surely if the disease were contagious it would exist in both at the same time, and to move from one to the other would be of little avail; however, such is the fact—the detachment moved, and not one other person was infected. I was informed how many died, but I cannot at present remember the exact number. The deaths are sufficient to shew the nature of the disease. Its local origin, and sudden disappearance on the change of situation, notwithstanding that at least such of the sick as were able to be conveyed followed in the rear, are, I think, satisfactory evidence of its possessing no contagious property. If the heads of the departments in the country had any, even the most remote, reason to believe that cholera was a contagious disease, surely they would, in a case like that I have just adduced, establish a quarantine, and not have allowed this infected body to join the head-quarters, at least till a clean bill of health could be produced; but no—they continue their march, arrive at Poonah, and hear no more of cholera, at least for a time. This is by no means a singular case, and

I doubt not, that, on reference to the reports of the army medical officers, many similar examples may be found. Cholera has made its appearance in transport, merchant, and other vessels, some time after their leaving the harbours of India; they proceed on their voyage, often, indeed, losing many men, but I will venture to assert there never was an instance where the ship, touching at any port, communicated the disease to a single individual. I am aware of the popular opinion that the *Topaze* frigate, touching at the Mauritius*, infected persons on that island; but we are informed by Dr. James Johnson, in his book on the "Diseases of Tropical Climates," that the fact was entirely disbelieved by the principal medical officers and others who were there at the time, and must necessarily be most entitled to credit.

For the last ten years, or more, an immense number of vessels have been trading between India and the different ports of England, many of which have left the different presidencies at times when the disease has been most rife; often has it happened that the labourers employed in shipping the cargo have fallen immediate victims, and still we have as yet escaped the pestilence: why, then, is it likely that there should be a difference in vessels coming from the Baltic? Certainly it would not be easy to answer this question. It is a common practice among the ships of war on the Indian station, immediately cholera appears on board, to weigh anchor and proceed to sea: is not this a satisfactory proof that, by naval officers, it is not believed to be a contagious affection? For surely a ship, howsoever good the accommodation, cannot be the best place to separate the clean from the unclean.

When the disease attacked the sixth regiment, at Colabah, in July 1828, its commencement was a remarkable proof against its contagious nature: it was in the midst of the most violent rainy season; not a case had for months been seen either in or near Bombay, when assistant-surgeon Campbell, in paying his evening visit to the hospital, found an old soldier, who had been some time under treatment for an hepatic affection, suddenly seized with cholera: he went to the opposite extremity of the build-

ing for the purpose of consulting with the surgeon, and found him busily employed with another man who had been almost simultaneously affected. Now it is physically impossible that these two individuals could have received the disease by contagion, because that which does not exist cannot have issue. From this beginning the disease proceeded, with unabated violence, until it proved fatal to sixty men and several women. It attacked a number of men who were labouring under, or convalescent from, diseases of the liver and bowels; none of whom, so far as my memory serves, recovered. Besides those in hospitals, others who were in excellent health were infected in the barracks. It is curious that, whilst the disease was committing such dreadful ravages amongst the soldiers, no instance of an officer's servant, or officer being attacked, occurred. This may be accounted for by their being less exposed to the vicissitudes of the weather, and, from possessing greater comforts, were less predisposed; not from their being separated from the diseased, because the officers were in the habit of paying daily visits to the hospital, and conversing with the men of their different companies who were dying, and the servants were in the constant society of their comrades in the barracks: indeed, it was often necessary for them to take their duty at the funeral parties, the distance which the corpse had to be carried being at least half a mile. They were thus exposed most powerfully to the contagion, had any existed. During this melancholy period, we had as many as two hundred and fifty men in the hospital out of seven hundred; it may, therefore, easily be imagined that the medical officers and attendants must have been constantly employed; and although we were with the sick the greater part both of night and day, and never deemed it necessary to use the slightest precaution against infection, yet we all escaped. The apprentices and dressers slept invariably in the wards, and always in the next bed to the worst cases. None of them were infected. We were allowed a number of orderlies from the barracks during the whole time the epidemic lasted; these were constantly employed performing various duties round the beds and about the persons of those labouring under cholera, but there was no in-

* See the letter on this subject in the present No.

stance of their being struck with the blight, if I may so term it. The nurses whose duty it was to attend the women admitted into the hospital, being scarcely ever out of the wards, had a like immunity. In fact, there was but one circumstance which, even by the most prejudiced contagionist, could be laid hold of to support the doctrine. A serjeant, who attended his wife, became slightly attacked, but was one of the few who recovered.

It is worthy of observation, that the number of fresh cases in the day bore a very near connexion to the state of the weather; for so sure as the day was clear, allowing the blinds to be thrown open and a free ventilation, together with the different effects upon the spirits of the men, induced by the change of atmosphere, there would be no one attacked; but perhaps the next day being wet the virandahs were closed, every thing inside was dark, damp, and miserable—then, indeed, the poor fellows breathing impure air, being weak and wretched, seeing their comrades dying all around them, were certainly predisposed, soon infected, and died. The pestilence, however, after remaining with us two months, gradually subsided as the monsoon terminated.

It will be seen that, although I have stated what I believe cholera *not* to arise from, I have not said what *is* the cause; nor, in truth, am I able to advance more than merely a suspicion of its being a poison circulating in the atmosphere—whence arising, or how existing, I know not. But I am fully convinced that certain circumstances, operating together, render individuals exceedingly liable to its attacks; amongst which are poverty, unwholesome or insufficient nutriment, despondency, fatigue, debility from previous disease, or whatsoever depresses mentally or bodily: thus the followers of a long-protracted and unsuccessful campaign, or the poor inhabitants of an over-populated and disaffected country, are particularly predisposed, and, when once attacked, have little power to resist its fatal tendency.

In proceeding, it now becomes necessary to describe the general appearances of the disease. As I have already hinted, it is liable to assume two distinct forms, which, being very different in character, but passing under one name, have, if I mistake not, caused considerable discre-

pancy amongst even Indian practitioners. The one approaches very nearly to the affection so named in England, which occurs generally in the autumn; it is attended with vomiting and purging simultaneously, the matters ejected being highly mixed with bile; extreme pain in the abdomen; sometimes cramps in the gastrocnemii, and great exhaustion; the pulse may sometimes be very small and weak, and the surface of diminished temperature; but on the application of the hot bath, and administration of a little diffusible stimulus, reaction becomes developed, and the patient may perhaps require the abstraction of blood, which, with a little calomel and opium, generally restores to health. Thus it is that persons seeing this form of disease in time readily cure the patient, and spread forth the doctrine that cholera is to be treated by bleeding, attributing blame to others who, seeing the disease under a different form, have not had recourse to the same measure. But I am convinced that if even this description of case be not seen in time, before the powers of life are too far sunk, bleeding will be inefficacious, at least until reaction shall have been restored by other means. Young healthy individuals are most liable to this species of attack, especially shortly after arriving in a tropical climate, and I have bled them myself with decided advantage. In fact, I repeat, if seen early, and occurring in healthy subjects, this is an exceedingly manageable complaint. Not so with that form where the patient, perhaps, having the moment before been attending to his ordinary duties, for instance, on sentry, has been suddenly seized with an inclination to go to the rear, attended with an uneasy sensation of the abdomen, and sickness at stomach. He passes, as he believes, a very copious evacuation, and perhaps may return to his post, to which he shall scarcely have got, ere he is irresistibly called again to the necessary; now, or perhaps before, he evacuates the contents of the stomach, mixed with a frothy mucus: sometimes he is by these operations so exhausted as to fall down on the ground. In this state he is found; and perhaps before the medical officer can see him, the pulse at the wrist will not be perceptible, but the skin covered with a clammy perspiration, with severe cramps in the abdomen and calves of the legs; the countenance

ghastly, and expressive of the utmost anxiety; the nose sharpened, the corners of the mouth drawn back, and the eyes sunk, with a depression under the lower lid. It is astonishing how soon this expression supervenes; and of so marked a character is it, that it were impossible for a person once having seen the disease not to recognize it even by this sign alone. Indeed, in a less degree it is perceptible before the other symptoms become violent; and I have more than once, whilst passing in the ward, or conversing with a soldier, detected the disease before the patient was himself aware of being infected, or at least before he made any complaint. The thirst is most insatiable, and the desire is generally for cold drinks. There is great restlessness, the patient never remaining in one position a minute, throwing his body from one side of the bed to the other; the purging continues incessant, the matters ejected being thin and white, and have been aptly compared to rice-water, but generally being very foetid. Nothing now remains on the stomach, and the individual, however strong, is sunk to the most extreme prostration; the finger-ends are shrivelled, as though they had been long immersed in hot water; the nails are of a dark black, or blue colour; the respiration difficult and hurried. The patient retains perfect possession of his mental faculties till the last, and is generally much influenced by surrounding circumstances; he will catch with great avidity at the most trifling expression of the medical officer or attendants. The disease sometimes runs its course in two or three hours; again, I have known it protracted to three days before the fatal termination. There is considerable difference in cases relative to the severity of the cramps; in some they are most excruciating, in others but little complained of; and I think generally the latter are the least manageable, as in them the powers of life are more sunk.

Dissection has thrown but little light on this disease; the large veins in the thorax and abdomen are generally gorged with blood, of a thin oily appearance, uncoagulated, and of a very dark colour, which issues in great abundance from the lungs and liver on being cut. The gall-bladder is always exceedingly distended with a thick dark

tar-like substance; the veins of the peritoneal coat of the intestines are most minutely injected. The mucous surface of the stomach and bowels I have rarely found inflamed, but there is a thick greyish secretion found in great abundance in the intestinal tube; there never is a particle of bile, or any thing bearing the appearance of fæces, to be discovered. I have often seen in the intestines long round worms, which, as well as the tape worm, have also repeatedly been passed by patients, both by vomiting and by stool; whether or not they had any connexion with the disease I am not prepared to say. The urinary bladder was always found empty, and collapsed. The pathology of the disease, then, does not appear to be much elucidated by dissection, but I entertain a very strong belief that chemistry will one day or other assist us much in this particular, for besides the stagnation, which is evident both before and after death, there is, if I mistake not, a material change in the quality of the blood; what that may be, or how induced, I will not attempt even to suggest, but I think a knowledge thereof might be of wonderful importance, and to this circumstance I would particularly direct the attention of the profession. So far, however, as we already know, the indications to be fulfilled are to support the powers of life, until by some means the balance of circulation can be restored, and then, by exciting the various organs to renew their suspended secretory functions, the disease may be overcome; but I am bound to confess that my own efforts to this end have been unavailing in an immense majority of cases;—nevertheless I have not yet learnt any plan better calculated to save the patient than the one we adhered to at the close of the epidemic. We were not so inhumanly blinded by prejudice as to persevere in what we saw ineffectual, but adopted means which had been serviceable in the hands of others; however, they were not alike so in ours, and after a fair trial we reverted to our original principles, and which I now recommend, not as the best that may be, but as the best which I know of.

On being called to a patient labouring under cholera, such as I have described, I would administer immediately a large dose of calomel, viz. twenty grains, followed by a draught, contain-

ing about two ounces of brandy, a little hot water, and two or more drachms of laudanum; a small quantity of sugar and spices may be added, if palatable to the patient: the calomel to be repeated every half hour, or hour, until the stools become bilious, or the evil symptoms subside; the laudanum and brandy, with the addition of the carbonate of ammonia at intervals, and in quantities to be regulated according to the violence of the vomiting, purging, exhaustion. &c. If the patient be much exhausted, he had better not be put into a hot bath; but if the attack be at its commencement, or not severe, it will be very beneficial; the temperature should be exceedingly high, 150 degrees, or more, for the skin is so deadened as to lose, in a great degree, its sensibility. As a substitute, the patient may be enveloped in blankets, immersed in hot water, in which the nitro-muriatic acid has been mixed; this measure, I think, I have seen of service. If neither of these means should be adopted, frictions should be used to the whole surface of the body, with strongly stimulating liniments. Six persons, at least, ought to be constantly employed. Sinapisms of mustard should be applied to the calves of the legs and feet. A large blister may be applied to the abdomen, but one of the ordinary kind will be of little avail, as it seldom vesicates. I have, therefore, known nitric acid applied, but have not adopted it myself. The cramps being so severe, the patient constantly calls loudly for some one to rub the belly, and therefore I usually order a liniment of spirits of turpentine, opium, and oil, to be used, which at all events produces slight temporary relief. The less the patient drinks the better; but the demand being so urgent, liquids cannot be entirely withheld; they should be warm and slightly stimulating. I knew one patient who rejected every thing but cold water; another whose demand was for gin; others drink in preference congee; and perhaps it is well in some measure to yield to this caprice. If under the measures adopted the extremities become warm, and the skin regains its elasticity—if the pulse increases in volume, the vomiting ceases, and the purging be diminished, or the matters passed be tinged with bile, a favourable result may be prognosticated, though the hope is often fallacious, as the patient is liable to re-

lapse. This leads me to remark, that the most incessant watching is requisite for the well-being of a case of cholera; and I am convinced, that when the disease is epidemic a number of patients die from the impossibility of paying them that devoted attention which they would receive were it a single case. In the event of the purging returning, of the cramps being renewed, or any other symptom occurring indicative of a relapse, perhaps a dose of the cholera mixture, which consists of opium, brandy, and spices, or the timely application of a hot bath, may ward it off, and therefore a patient in cholera ought never to be left for a moment, as a quarter of an hour lost is irretrievable. Should the symptoms I have mentioned pass off, and be succeeded by a re-action of proportionate violence to the previous depression, then, but not till then, would I recommend the use of the lancet; and the extent to which the depletion must be carried is to be relative to the fever and local determination. The brain and liver are generally the organs affected in what may be termed the sequela of cholera. In one case which I attended, the brain became inflamed to an exceedingly violent degree, after a smart attack of cholera; the patient was bled largely both from the arms and temporal artery, with other depletory measures, before the febrile excitement could be subdued, and though ultimately he recovered his bodily health, he was an inmate for two years of the lunatic asylum. Another instance occurred where cholera was succeeded by fever of the pure typhoid character, which continued three weeks before the man became convalescent. One man was attacked with jaundice, attended with much fever, and after lingering many weeks, died a maniac. At Halifax, Nova Scotia, a man of the 34th regiment was admitted into hospital on the 13th September, having been drinking for some days before; he had incessant vomiting and purging, severe cramps, and great exhaustion; the countenance sunk, the pulse very small and weak, and the skin cold; it was considered by the medical officers a genuine case of cholera morbus. By the administration of appropriate measures re-action took place; there was considerable pain in the head, and heat of skin, attended with copious bleeding from the nose; the surface of the body became of a deep yellow hue,

petechial spots appeared on the limbs and breast, the tongue became dry and brown, large quantities of blood were passed by stool, and the patient sunk under these accumulated evils in seven days.

On dissection, the viscera generally were seen to partake of the yellow hue; the liver, except in colour, seemed healthy; the gall bladder was empty and collapsed, the internal coat of which, as well as of the cystic, hepatic, and common ducts, were of a red colour. The peritoneal coat of the intestines was throughout more or less injected; but on opening the stomach and intestines, the internal coat was of a dark or chocolate colour, which seemed to be caused by an extravasation of blood into the cellular tissue connecting the mucous to the muscular coat; the vitality of the mucous coat appeared to have been destroyed, as, with the point of the finger, it could easily be separated from the others; this appearance was less extensive in the jejunum and ileum than in the other parts of the alimentary canal. For this case I am indebted to my friend, Mr. Rankin, Surgeon of the 31th; and as it illustrates so well the position of cholera being merely a stage of fever, I deem it an invaluable addition to the present essay. By the description at the commencement, taken from the register, I am convinced that the case approached very near to the Indian cholera; and in the latter stage, in which I saw the man, there was the most exact resemblance to some of those alluded to above. The last case to which I shall allude, after suffering much from inflammation of the liver succeeding cholera, died dropsical. Other cases still fresh in my memory, after surviving the attack of cholera, remained long in a very precarious state. I am therefore inclined to believe cholera to be merely a stage of fever, such as Dr. Armstrong would have termed the congestive. It has never been my lot to witness the yellow fever, but I entertain a strong suspicion that there is a close connexion between it and cholera morbus; however, as I only profess to treat on what I have seen, I must here let the matter rest, at least for the present. Although little can be done in this dreadful disease when once established, for even under the most favourable circumstances a very large proportion of cases

terminate fatally, still there are many measures which, in a prophylactic point of view, should not be neglected, for, being adopted, they are attended with the most beneficial effects. I therefore would suggest, that when cholera appears as an epidemic, especial care should be taken to preserve the animal vigour, which is to be effected by a wholesome nutritious diet, rather stimulating than not, being careful to avoid whatever is indigestible, or likely to disagree with the stomach; therefore all rich viands should be abstained from, together with pastry and vegetables, avoiding excesses of quantity as well as quality, either in eating or drinking; that every person who has the means, should take a moderate quantity of wine or spirits daily; that the clothing should be warm, particularly about the abdomen and feet; that the bowels should be kept gently open, avoiding scrupulously purges of a drastic nature, at the same time being careful that the liver secretes properly; the mental vivacity is likewise to be sustained, avoiding all causes likely to produce despondency or lowness of spirits—in short, by every means to endeavour as much as possible to steer clear of debility, howsoever induced, it being the grand predisposing cause of cholera; and I venture to assert, that these measures will have infinitely more influence in saving us from its invasion than the quarantine laws, be they ever so strict.

I have hitherto said little upon the efficacy of general bleeding in cholera morbus, for though the adoption of it has been highly lauded by some persons in whom I have great confidence, it is, nevertheless, contra-indicated according to the principles which I entertain of the treatment. This difference of opinion may arise, as I have already stated, from those gentlemen having witnessed a different form of disease; and this is exceedingly likely to be the case according to the different stations occupied; for I think it were scarcely possible to observe a greater difference in the appearance of any body of men, than existed at one time between those of two of his Majesty's regiments, the one at Poonah, and the other at Colabah: those at the former quarter were stout, fresh coloured, and possessing almost an European vigour and health; the others were emaciated, pale, and debilitated. The climate of the two

places is sufficient to account for the whole; at Poonah the atmosphere is rare, dry, and elastic, the nights cool and delightfully refreshing; whereas at Colabah—in fact any where in what is called the Conean, or low country—the atmosphere is moist, heavy, and hot, relaxing to the greatest degree; and we had ample opportunity of judging of its effects upon the constitutions of the soldiers. We had the utmost difficulty in proportioning the doses of medicines to the constitutions of men who, under other circumstances, would have borne any treatment. In such an irritable state was the mucous membrane of the bowels, that one drachm of salts would produce twelve or fifteen evacuations; and I have known more than one case of cholera certainly induced by the most minute doses of salts or castor oil; on the other hand, when we had been even a short time in the Deccan, the men improved wonderfully, and required more than the ordinary doses of medicine to affect them.

To return, then, to the subject of bleeding; I can only add, we tried it in several instances, but only once with success. In this case the man was seen early, but slightly affected, and recovered. In fact it seems unnecessary to say more upon the subject, for if there be no blood in the arteries of the extremities, I cannot conceive how it can be expected that any should follow the puncture of a vein; and cases where there is free circulation in the extremities, are not those of severity, or at least are seen before the severe symptoms have come on. To shew how suddenly the disease appears, and how soon the circulation becomes suspended, I will adduce one more case.

I had seen a patient one morning at ten o'clock, who had been long suffering from chronic liver complaint and stricture; he was anxious that morning for me to discharge him, as he felt himself better than he had been for some time, and thought air and exercise would be of service. At half-past twelve I was called to the hospital to see this man, who had been attacked with cholera. Perhaps half an hour had elapsed from the commencement till I saw him in company with Dr. Strachan, Inspector-General of Hospitals; we found him completely prostrate, with severe spasms, incessant purging, but no vomiting; the skin of the extremi-

ties was cold and moist, whilst over the abdomen it was hotter than natural; not the slightest pulse could be felt at the wrist. Dr. Strachan desired some stimulus to be given him, and the man wished much for gin; he drank about four ounces of it, which produced for a few minutes a small thread-like pulse; other means before alluded to were adopted, but the man died in a few hours. Indeed, to think of bleeding a person under such circumstances would be contrary to every principle of common sense. It is not the quantity of blood in cholera which requires to be diminished, but the circulation and quality of it which require to be changed. Some sudden impulse should be given to the heart, in order to restore it to action, whereby alone the internal parts can be relieved of the congestion, and the balance restored; probably electricity might have the effect, but I have never had an opportunity of trying it.

ENGLISH CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

THE two following cases of severe cholera having fallen to my charge during the last three weeks, and as I am daily consulted for the relief of diarrhœa, I am tempted to ask the question whether “an epidemic constitution of the atmosphere may not be at present prevalent in London?” I never remember these disorders so frequent at this season of the year as they are now.

On Monday morning, October 31st, A. B., about thirty-two years of age, kitchen-maid in a family residing in Bryanstone-Square, got up to her usual labours about seven o'clock. She had scarcely arrived at the bottom of the stairs when she was seized with violent abdominal pain, vomiting of clear fluid, purging, and insensibility, or collapse. She was carried to the upper part of the house and laid upon the bed, the family believing her to be dying. I arrived to her assistance a little before eight. She appeared, certainly, more like a dead than a living body, and had very much the semblance of a shrivelled up old woman (her sister said that she

should not have known her). She answered every necessary question, but in a whisper; made no complaint of pain. I could not feel the pulse at the wrist, her hands were bloodless, and, with the feet, were quite cold. She complained of feeling intensely cold, and her head was like "cold marble;" there was also present a kind of convulsive sobbing. I covered her up with blankets, had five long stone bottles of hot water placed round her, and commenced the administration of stimulants. I considered it necessary, during one hour and a half (which was the time I was with her before I dared leave her) to give about two wine-glassfuls of brandy, five or six teaspoonfuls of spirit of sal volatile, and the same quantity of spirit of lavender, combined with a teaspoonful of laudanum, with two or three cups of warm tea. The stomach retained all this; there was neither vomiting nor purging. As soon as she was sufficiently recovered, she informed me that she had not been very well for some days, but during the night she had been harassed with pains about the insteps and back of the legs.

10 o'clock.—I found her much more comfortable, and, under the influence of the brandy, &c. she had taken, her pulse was full and bounding, skin hot, and her tongue, which was before quite clean, and I may say swollen, was now brown in the centre and dry. I expected a violent attack of fever, and that it might be necessary to remove her from the house; but having an appointment with Dr. Nevins on at one, I decided on leaving the case for his opinion, and I directed her to be kept covered up, to take warm tea, and prescribed as follows:

R Hydrargyri Submuriatis, gr. v.
Extr. Colocynth. Compos. gr. x.
Ol. Menih. Pep. gtt. i. M. it. pil. iij.
statim. sumendæ, c. dose, misturæ
sequentis.

R Magnes. Sulphatis, ʒj.
— Subcarbonatis, ʒj
Aque Menthæ Piper. ʒvj. M. ft.
Mistura Sumat. quartam partem
omni horâ donec alvus responderit.

1 o'clock.—I met Dr. Nevins on. The woman was in a most profuse perspiration, complaining only of slight pain in the head; in fact, all the symptoms of alarm had subsided.

She was perfectly recovered, and able to resume her usual occupation in two days.

Friday morning, November 10th, about nine o'clock, I was requested immediately to visit —, a cook, in Gloucester-Place. I found her complaining of burning pain at the pit of the stomach, with constant vomiting and purging (but I could not obtain any satisfactory account of the colour of these evacuations), and crying out with cramps at the back of the legs, beginning at the toes and extending up the thighs; the instant she put her hands out of bed, her fingers were clenched towards the palm, and the pain extended to her shoulder, &c. She had not been very well for a day or two, but was seized suddenly during the night, and had been writhing in tortures for some hours. Her countenance was very dark and ghastly; the housekeeper said she could not have believed so great an alteration could have taken place in so short a time. The fœtor was very great (nearly to excite nausea). I threw open the window, and directed her to be covered over with blankets, hot bottles to be applied, with friction, &c. and she took without delay,

R Hydrargyri Submuriat. gr. v.
Pulv. Rhei, gr. x.
Olei Carui, gtt. ij. M. ft. pilulæ, iij.
statim c. haustu sequente sumendæ.
R Spiritus Lavendulæ Compos. f. ʒij.
Spir. Camphoræ, ℥xx.
Tinctura Opii, ℥xx.
Aque Carui, ʒx. M. ft. haustus c. pilulis sumendus et post horam repetendus.

11 o'clock.—I again visited her, and met Dr. J. Clarke, of George-Street, he having been sent for by the family. The patient was now very much better; she had neither vomited nor been purged since taking the medicine; the cramp in the legs still continued; the pain at the stomach was less, but she was continually moving about in bed. Clarke was of opinion that she was much relieved by the means adopted, or he would have sent a message to Dr. Russell, who resides in the neighbourhood. Dr. C. advised that the draught should not be repeated for an hour, and directed a fire, to assist in ventilating the room.

1 o'clock.—I visited her again. She had relapsed; her thirst for cold drink had been intense, and she had indulged in some toast and water, which had been rejected by the stomach, and the cramps were increasing. I sent her directly,

Ol. Rorismarini, gtt. xx.

Magnesiae Subcarbonatis, ℥j.

Aq. Puræ, ℥iss. M. ft. haustus.

2 o'clock.—The draught had done her good, and I now repeated it.

4 o'clock.—Better; crying out occasionally with cramp, &c. The draught to be repeated.

6 o'clock.—She now complained only of great soreness all over the body; the cramps less frequent, but the moment she exposed her hands she had tingling and numbness of the arms. She had not voided water for upwards of twelve hours. I inquired what effect the medicine produced? She said, "every dose did her good."

R. Ol. Rorismarini, f. 3j.

Magnesiae Subcarbon. 3j.

Aq. Puræ, f. 3vj. M. ft. mistura, sumat 4tam partem 3tiis vel quartis horis.

Saturday morning, Nov. 12th.—Very much better; the cramps had ceased; her knees were so stiff and painful that she could not bend them. Urine had been abundantly passed during the night. To remain in bed.

R. Ol. Rorismarini, mxl.

Magnesiae Subcarbonatis, 3j.

Aq. Puræ, 3vj. M. ft. mistura, sumat 4tam partem 5tis vel 6tis horis.

Sunday morning, Nov. 14th.—Quite recovered. Her bowels had acted once freely, but comfortably. To get up, but not to leave her room.

I do not adduce these two cases (far from it) under the name of Cholera Indica, Asiatica, or Contagiosa; but I must maintain that the first might be denominated a mild case of cholera asphyxia, the latter of cholera spasmodica.

THOMAS BUSHELL.

OBSERVATIONS

ON THE

CHLORIDES OF LIME AND OF SODIUM,

And Suggestion of some forms of Application, &c.

*To the Editor of the London Medical
Gazette.*

SIR,

It is not without astonishment we contemplate the little favour enjoyed in England by public hygiene. On the continent it is the subject of particular

study, and of general attention, and has given rise to many voluminous works of surpassing interest. Periodical publications are exclusively devoted to it; councils and commissions of men of science are established every where purposely for its superintendence, and statesmen are deemed incapable, or neglectful of their duty, who do not devote a due proportion of time to its encouragement. The remarkable increase of longevity in England of late years is principally attributable to those improvements in hygiene which, although unsought for, have followed the advance of the inhabitants in comfort, because in a certain degree inseparable from it. But if any one should deem these improvements sufficient, let him read, were it only the index, of the "*Annales de l'Hygiene*," and he will see the number of practical applications of science to the welfare of mankind which the public never hear of in England, although it is the fatherland of philanthropy*. However, the scourge now approaching will be an imperative monitor in favour of public hygiene, to whose lore it directs us as emphatically as a statue in a cemetery points to the legend of a tomb. Public hygiene requires not only men of science to invent and suggest, but the great mass of the nation to read and co-operate; and we must hope for the day when it will beneficially supplant that study of "Buchan" and the medicine chest, by which so many people drug themselves into disease, and not a few to death.

I hope these observations may be excused, though they may appear too grandiloquent, if considered only as prefatory to the humble suggestions I have to present; and even the latter may be deemed supererogatory if the cholera be considered as neither contagious nor infectious. However, the great majority of men of science are of a different opinion, and of the justice of this opinion we shall but too soon have personal experience. In many places where this fearful traveller has arrived, he has appeared at first in disguise, and has deceived the inhabitants by his equivocal character. Perhaps the peculiar locality, or the unfavourable season, has

* There are some peculiar forms of phraseology in this paper, which is from the pen of an intelligent foreigner; but as they are generally very expressive we have left them unchanged.

prevented his epidemical and contagious nature from appearing distinctly. But, after a certain time of incubation, when warmer and more relaxing winds have begun to prevail, he has rushed forth in all his epidemical fury, and falling upon some class of men of defective vitality, caused either by depravity or poverty, has revealed all his contagious banefulness.

Of all the chemical agents that have been employed to destroy effluvia, none can compete with the chlorides of sodium, lime, and potash. It is not, therefore, surprising, that on the appearance of cholera in Europe, that truly praiseworthy chemist, Labarraque, should have been applied to on the subject of his antiseptic process. Labarraque advises two glasses of water to be daily given, containing from thirty to forty drops of chloride of sodium; the hands and face to be washed with a solution of it; baths, with six or eight ounces of the liquid chloride in each; plates, containing the antiseptic liquor or powder, to be placed at the doors and on the mantel-pieces; and curtains of coarse linen to be hung before the windows, which are to be kept moistened with the chloride. Desirous of promoting this mode of purification, I wish to recommend some precautions in its use, and next some more convenient forms of application.

The chlorine which is evolved in the manner above recommended—a destroyer of colours, odours, and effluvia, in its unmixed state is also a destroyer of life. We know how rapidly an animal dies when immersed in a vessel of chlorine gas. We have also the examples of an English physician who died of a disease of the lungs occasioned by his experiments on this gas, and of several chemists who have suffered from the same cause. Although chlorine has been employed in the treatment of some diseases of the lungs, and although when diffused in a small proportion in the air it has not appeared deleterious, not only it cannot but deteriorate in some degree the natural atmosphere of respiration, but when employed in the abundant manner recommended above, we may fairly suppose that it may become highly deleterious, particularly to persons very young, very old, or very weak. We may suppose this to be the case even when no palpable effects are immediately produced, for may it not oppress the powers of life, just as we see in houses

either situated in a low or marshy locality, or near the common sewer, the miasmata slowly destroy the inhabitants, perhaps without producing even one single well characterized attack of fever?

To obviate, as far as possible, these objections, we would recommend the following measures:—Whenever it is desired to cleanse a house, or a room, of effluvia or impurities, a large quantity of one of the chlorides should be placed in the most favourable state for the evolution of the gas. Every body should then withdraw, taking care to remove all the coloured articles of furniture, gilt frames, &c. liable to be injured, and the doors and windows be shut as hermetically as possible. Thus the place will be more speedily purified; and doors and windows being thrown wide open after a due lapse of time, no person's health will be injured. When, on account of the presence of the sick in the same room, or in the same house, a constant evolution of gas is required, flat dishes full of the chlorides should be put only where there are the greatest currents of air, placing the dishes in as high a situation as possible; as it has been found that otherwise the gas, which is heavier than the atmosphere, will not mix sufficiently with the air, and only lie in a more concentrated stratum on the floor. If, from time to time, there is a suspicion of too large a proportion of chlorine existing in the room, let a little liquor ammonia be thrown on the floor, and the rising of a white vapour will reveal the existence of an excess.

When you walk through an infected place, or approach a person labouring under a highly-contagious disease, it has been recommended to keep a handkerchief to the mouth, wetted with the disinfecting liquid. This obstructs the speech, whilst the gas inconveniences the lungs, and the protection is liable to be removed in incautious gesticulation. I have had a simple contrivance made to send abroad, of which the design is subjoined; it has the advantage of leaving the speech free, and of being a protection from deleterious emanations, without depriving the lungs of communication with the usual atmosphere. This mask consists of a wire coming from the back of the head to project before the mouth, where it terminates in a ring, furnished with points, to which a sponge dipped in the solution of chloride of sodium may be attached. A thin and short band of brass crosses the wire, and fixes

this simple apparatus to the head immovably. Being elastic, this mask fits the head of every adult, and may be put on and taken off in a second by each

person going into the sick room, and causes no inconvenience in any movement of head or body. Besides its use in contagion, its adoption would save the lives of nightmen, who often sink in their disgusting duty.

Salts containing an excess of acid, when mixed in the dry state with chloride of lime, cause the slow evolution of gas by the new combination that arises. Mr. Garden, whom I have consulted on the subject of this letter, and whose chemical acumen often rests on ingenious minutia from more important pursuits, has had the kindness to construct a smelling bottle containing a powder of the above description. Hung by a ribbon round the neck, the heat of the body will favour the evolution of the gas when the stopper is removed. A more

effective protector than camphor and other agents carried on the person, this precaution will not alarm the sick friend or the patient. Should the cholera, or any other contagious disease, become very virulent, the medical attendant might wear cotton gloves, with the end of index and next finger of the right hand cut off. The gloved hands being dipped in the disinfecting solution, the pulse, or any other part of the body of the patient, might be examined without fear, the gravity of the fluid making it constantly flow to the apices of the exposed fingers. Nurses may wear oil-skin gloves, and an oil-skin smock-frock, closing hermetically round the throat, wrists, and over the chest.

Besides the chlorides many other "disinfectants" exist, and not a few of these whose source of power must remain concealed. It would appear that most bodies that emit strong odours possess a virtue against contagion. The cholera has had little influence in places where the forests in the neighbourhood have spontaneously ignited, and the wood has remained smouldering over the fire. It will be said, perhaps, that here heat and the pyroligneous acid have played important parts; but manufactories of snuff have been untouched by the cholera raging around, so that smoking has been enjoined in despotic countries where it was previously forbidden. Nor have examples been fewer during epidemics of the plague, where the centre of a town, the vicinity of the most nauseous trades, have remained free from the pestilence raging around. Therefore, the general confidence in the fumes of acetic acid, when not carried too far, is not without some reason for its support. To meet the wish of some friends to possess an antiseptic of this description, I have applied the acetic ether to the beautiful philosophical fumigator first imagined in Germany, and now manufactured in this country by Mr. Garden. It is constructed on the knowledge of the singular and well-known fact, that a platinum wire once ignited, remains in this state as long as it is held over spirit or ether. Thus a platinum fillagree, appended to a glass rod that dips into a scent-bottle full of acetic ether, may be made to diffuse it in the form of a very agreeable and exhilarating vapour throughout the room of an invalid.

HENRY BELINAYE.

Berners-Street, Dec. 5, 1831.

CHARACTER AND TREATMENT OF CHOLERA*.

To the Editor of the London Medical Gazette.

SIR,

At a period of excitement like the present, when not only the public generally but even the profession are in no small degree alarmed at the progress of malignant cholera, it becomes every one, who wishes well to the best interests of his species, to do every thing which may lie within his means to render the subject of these fears less the occasion of alarm. It has occurred to me that, in some respects, it was in my power to co-operate somewhat to the attainment of this most desirable object; and should you find space in the next number of your Gazette for the enclosed letter to Dr. Barry, and the subjoined remarks by which it is accompanied, you will oblige

Your obedient servant,
C. NEGRI, M.D.

26, Poland-Street, Oxford-Street,
December 1, 1831.

London, November 29, 1831,
26, Poland-Street, Oxford-Street.

Dear Sir,—After all I have read on the subject of malignant cholera, and after having paid particular attention to the character of the disease, it struck me very much how remarkable was its resemblance to that class of diseases so well described by Torti, in his valuable work entitled "*Francisci Torti Mutinensis Therapeuticæ Speciales ad Febres quasdam Perniciosas inopinato ac repente lethales, una vero China China, peculiarimethodo ministrata, sanabiles*;" which was published, for the first time, in 1709.

Speaking of the character of those fevers, Torti says, "The pernicious intermittent, more especially that wearing the tertian form, kills about the beginning of the paroxysm, when it is accompanied with violent bilious vomiting and purging of bilious humours, equally vicious both in quality and quantity, being sometimes clear, at others coloured, and occasionally of inspissated greenish bile; to which vomiting and purging are added, hiccup, a

hoarse sonorous voice, hollowness of the eyes, pain of stomach, small sweat upon the forehead, weak pulse, and cold or livid extremities—in one word, all the symptoms which usually mark *cholera morbus*; from which, however, this, as it were, *choleric affection*, is to be distinguished, since it is a mere symptom of the fever, the period of which it follows, as a shadow does a body."

These pernicious fevers he distinguishes into different species, according to the peculiarity of their symptoms, and I was much surprised in reading the two following descriptions of what he calls "*febris perniciosa cholericæ*." At the fourth, or, unless I am deceived, the fifth accession, such violent, frequent, and copious vomiting supervene, together with purging of bilious, serous, and corrupted matters, at very short intervals, that the patient becomes almost exhausted, universally chilled, lies supine, as though unable either to sit erect or turn on either side, with a pulse almost abolished, sunken eyes, hiccup, and difficult breathing.—"The wife of B. G., after having suffered from two paroxysms of a simple tertian, in which pain in the bowels, vomiting, and diarrhoea were such prominent symptoms that their intermittent character was almost overlooked, sustained a third attack still more severe, accompanied with acute pain in the stomach and intestines, constant vomiting, purging of immense quantities of watery fluid; in consequence of which she became cold and pulseless, with a mortal pallidity of countenance, sunken eyes, pinched nose, and collapsed temples. Her disease was regarded by every one as choleric, and her state was considered hopeless. I was, however, sent for, and, upon examination, found the patient almost destitute of pulse, scarcely able to speak, complaining much of intestinal pain, and so cold that I was wholly unable to decide whether the disease were fever or ordinary choleric."

Then, as to the cause of the irregular appearance of these pestilential fevers, he says, "These fevers, however, are, comparatively speaking, less frequent than the mild intermittent; so much so, that, in some years, physicians of respectable practice, have no opportunity of witnessing them. At the same time, however, I dare say, that, in some close states of the atmosphere,

* The original extracts were sent for insertion with the translation given by Dr. Negri; but from the late period at which they were received it has been impossible to comply with his wish by inserting them.

more especially near the dog-days, and after the autumnal equinox, they are so prevalent as to appear almost *epidemic*."

No direct mention of pernicious agues is made by preceding writers, with the exception of Ludovicus Mercatus, first physician to the Kings of Spain, who has given an accurate description of the nature and treatment of pernicious tertians. To give you a proof that the class of diseases described by Mercatus is quite the same with that which Torti depicts, let me transcribe the following passages from that author:—

"There is a certain pernicious tertian which simulates the character of an ordinary tertian ague, but is most fatal, and complicated by many most perilous symptoms." Then, dividing these fevers into different species, according to the peculiarity of their symptoms, he says; "the third form arises from the depravity of the humours, not from their putrescency, in consequence of vicious food, which is also the cause of *cholera morbus*, a disease that *very frequently lapses into pernicious fever*, as Valcrius very properly asserted; or it depends upon that fervent and depraved habit of body which glutinous and vitiated bile produce."

Many other points of resemblance with the present malignant cholera may be seen in Torti's Book, *lib. ii.* which is a complete commentary on Mercatus; till, at last, in the eighth chapter, he takes up from the celebrated English author, Richard Marton, the following passage. "When the febrile poison possesses an emetic as well as a cathartic nature, the patient is affected with frequent vomiting and purging; and unless its virulence is counteracted during the first stage of the fit, *cholera morbus* is formed, and the fever progresses without manifesting itself either by the *pulse*, the *temperature*, or the *urine*. In the meantime the stomach or bowels, or both, mortifying from the intense acrimony of their contents, the patient either rapidly yields to his fate, or, after a few deceitful respites, the same cruel and fatal symptoms re-appear in a more aggravated form at the next paroxysm, unless, by a seasonable exhibition of the specific antifebrifuge, they are dissipated."

And, lest periodicity, which all these quotations refer to, might be supposed to indicate the dissimilarity of these affections to malignant cholera, I beg to

refer you again to Morton's authority. "Among" (says he) "the innumerable symptoms attending these fevers, there is none which may not rise to a great height, endangering the life of the patient, so that *typhus fever* (masked in its stages of cold, heat, and sweating) supervenes, rendering it impossible to be distinguished by the *urine*, *temperature*, *pulse*, or indeed any other means; but, concealed under the appearance of cold, vomiting, diarrhoea, *cholera morbus*, colic, or other disease, not unfrequently mislead the physician. These symptoms, indeed, may be plied with the ordinary remedies, but in vain; for, after the first accession, the following exacerbation approaches, with symptoms either equally or more severe; so that, like the stone of Syphilis, the physician labours to no purpose, and the patient pays the penalty of his attendant's ignorance or inattention by the sacrifice of his life."

In addition to Morton's authority on this point, if Torti's work be consulted, many sentiments of a similar nature will be found.

But now comes, after all, the most important point for your consideration. What is the method of treatment in this class of diseases? As you may have already seen from Morton's last extract, the *anchora sacra*, on which we must rely for curing them, is bark, as may be seen by the following passage from Torti's work, *lib. ii. cap. i.*

"Indeed, without any feeling of partiality, or without laying any stress upon my peculiar views, which I consider of small moment, I look to bark to rescue my patients from a destruction which, under any other treatment, is inevitable, but which I can promptly and effectually prevent by means of this agent. And it is useless to ask, whether, in cases of danger threatening death, the cause of the ague be wholly or partially removed, and whether the cure be only palliative or permanent, since he that is in *articulo mortis* is rescued from destruction in whatever way his cure may be effected. If this object can be attained, I leave the *modus operandi* of my remedy for others to explain. When I can obtain a safe and certain cure in all cases, even the most hopeless, by a timely employment of *Peruvian bark*, I pass over all theories without respect, believing them to be very generally deceitful.

From all this it appears, that the point of importance is, to give *bark* as soon as we can, and in *large quantities*. Torti himself being ill with one of these fevers, says, "me metipsum epotis uno haustu six drachmis illius (Corticis) a morte imminente illico evasi, et etiam nunc vivo, et etiam nunc scribo,"—lib. i. cap. i. We employ in general the bark in those diseases in Italy, in doses of two or three drachms every second hour, or more, and oftener, according to the severity of the symptoms. Sometimes it is given in tincture, equivalent in strength to that dose of the *powder*, and it has been thrown up into the *rectum* in the form of *injection*, when the dose requires to be very large and frequently repeated. Morton mixed sometimes bark with a certain quantity of laudanum when there were vomiting and profuse purging. We use the same method, and I found it very beneficial in two cases of that kind which occurred to me in Italy. The best vehicle for bark in this instance is wine and water, or what is better, in my opinion, cinnamon water. I should object to the use of the sulphate of quinine because I tried it once, and it partially failed. Morton, in certain instances, bled his patient to relieve the circulation, and then he gave bark.

Having deemed these facts of considerable importance, and having now taken the liberty of laying them before you, I beg to ask first, whether you think that the *malignant cholera* of our days belongs to the same class of diseases which was seen by Mercatus in Spain, by Torti in Italy, and by Morton in England; and, secondly, if you think that bark ought to be fairly tried in cholera, *according to Torti's method*?

As bark has been since Torti's time considered as an *infallible* remedy in these *febres perniciosæ*, I dare say, that the same drug might be found of some efficacy in cholera, if *judiciously* administered.

You must not, dear sir, however, think me either presumptuous, or as pretending to the possession of a *specific* for this dreadful scourge; and may I request, that after you have directed your attention to what I have written on this matter, you will have the kindness to send me your opinion on the points which I have now submitted to your notice.

Believe me always truly yours, &c.

C. NEGRI, M.D.

OBSERVATIONS ON THE CHOLERA MORBUS, AND THE PREVENTIVE MEANS.

To the Editor of the London Medical Gazette.

SIR,

AT a period when the public attention is so much excited by the distressing accounts of the cholera morbus, and of some individuals in Northumberland having been afflicted by this alarming disease, it is the imperative duty of every medical man to impart whatever may be the results of his own reflections, with the hope that some useful practical results may arise. It is the subject of inquiry, whether the disease is to be considered contagious or infectious; by the former I understand such diseases as can only be imparted by actual contact; by the latter, all diseases where miasma are produced, and diffused into the surrounding atmosphere, and by this medium communicated to such constitutions where there exists a predisposition: it is to the latter I presume that the cholera morbus is to be referred.

I understand that in those countries where the cholera morbus has prevailed, it has been preceded by an influenza similar to that which we have lately experienced in this country; and I have been informed by some highly-respectable practitioners, that those who have previously suffered an attack of influenza, are more predisposed to the action of the cholera morbus. It has been generally noticed, that when the symptoms of this complaint have made their appearance, if a copious perspiration be produced, the greatest advantages are subsequently experienced from the employment of such powerful stimulants as opium, brandy, &c. All the symptoms evince great constitutional debility, the energies of life depressed by the poisonous miasma, and generally accompanied by the most excruciating spasms. The post-mortem examination evinces the stomach and intestines to be loaded with depraved matter, and an acid suspected to be acetic; and Dr. Davy remarks, that there is a great deficiency of carbonic acid in the process of respiration.

These observations lead me to submit to the public consideration a plan of

treatment, which I think ought to be generally adopted as a preventive, by destroying any predisposition in the constitution to take on the complaint. In the city where I reside, we have the incalculable advantages of public warm springs, by which the healthy condition of the surface of the body may be preserved. In a work I have lately submitted to the public, relative to the influence of the *Barbadoes Green Naphtha*, I have introduced some observations on the process of digestion, in which I have endeavoured to demonstrate, that the solvent principle in the stomach is the sub-carbonate of soda secreted by the middle portion of that viscus; whilst the hydrochloric acid, which is intended by nature to effect a subsequently separatory operation, results from the pyloric portion of the same organ: the contents of the stomach being found depraved and acetic acid evolved, demonstrate that the active solvent principle is not properly secreted; and as carbon is the most powerful corrective principle we can with safety employ in such cases of animal or vegetable composition, it becomes of importance to introduce it in that form in which it will most readily mix with the animal fluids. It is on this account that I earnestly recommend the *Barbadoes green naphtha*, in a weak solution of the carbonate of soda in water, to be taken every morning. By a continuance of this plan, the deficiency of carbon noticed by Dr. Davy would be supplied, whilst the important process of digestion would be carried on with results conducive to health, and thus constitute the best preventive as to any infectious complaint.

Yours respectfully,

C. H. WILKINSON, M. D.

Sydney-Place, Bath,

IMPORTATION OF CHOLERA INTO THE MAURITIUS.

*To the Editor of the London Medical
Gazette.*

SIR,

I BEG to enclose an extract of a letter I have received from a gentleman who held a high official situation at the Mau-

ritius when cholera made its appearance there: it bears directly upon the disputed point of importation.—Your's,

A. C. HUTCHISON.

Duchess-Street, Nov. 20, 1831.

November 16, 1831.

I PRESUME your query originates out of the assertion made in a letter signed Omega, in the *Courier* of the 10th inst. that the cholera prevailed at the Mauritius previous to the arrival of the *Topaze* on that station; upon which it is attempted to overthrow one of Sir Gilbert's proofs in support of his belief of the communicable nature of the disease by persons and things. I was particularly struck with it when I read it, and can assure you that no case of cholera was heard of at the Mauritius until nearly three weeks after the arrival of the *Topaze*. This vessel anchored in Port Louis harbour, on the 30th or 31st of October, 1819, and the first case of cholera that occurred to my knowledge was on the 19th of the ensuing month of November, in the person of a negro belonging, I believe, to the establishment of a Mr. Lucombe, who was engaged in removing goods to and from the quay, weighing them, superintending their landing, shipment, &c. I cannot take upon myself to say whether any cases of cholera occurred on board the *Topaze* after she left Trincomalee, but I think the number of convalescent cholera cases that were landed at the Military Hospital in Port Louis, was sixteen.

Too much time has elapsed to enable me to say whether the extract from Dr. Burke's letter be a faithful one or not, but of this I am certain, that the larger proportion of the French practitioners believed the disease to be infectious, and to have been introduced into the Island by the *Topaze*; and that, among the inhabitants, the belief was universal. If the documents of the Colonial Office be examined, it will be found that a violent controversy arose out of the difference of opinion between a Dr. Guillemeau, a member of the medical committee, and Dr. Burke, as to the character of the disease; and that the unanimity of opinion referred to by Dr. B. in the extract made from his letter, was not so perfect as Omega would have it believed.

A CASE OF
ULCERATED NÆVUS,

Successfully treated by the new Operation.

By MARSHALL HALL, M.D. F.R.S.E. &c. &c.

MR. HEMING, to whom I am already so deeply indebted, has again afforded me an opportunity of observing the effect of puncture in the cure of nævus. The case was doubly interesting from combining ulceration with the ordinary circumstances of that affection.

The tumor was oval, about one inch and a half in length, and three-fourths of an inch in breadth. The central part was undergoing the ulcerative process; around the ulcer the nævus existed in the form of a ring, about one-sixth of an inch in breadth. The edges of the ulcer were ragged, and slightly phagedenic; the surface of the ulcer was *malimoris*, and had bled from time to time. The nævus rose about an eighth or a tenth of an inch above the surface of the skin.

A common broad needle, with cutting edges, was passed through the substance of the nævus, at its base, and under the ulcer, from side to side, in every direction. Several punctures were made, but one would have been sufficient.

In the course of one week the ulcerative process had undergone the most interesting change into the adhesive. No better, or more beautiful illustration could be presented of the *Hunterian* doctrines. The ragged edges became smooth and white; the ulcerated surface covered with a film of coagulated lymph. In a few days more the whole ulcer was completely healed.

As a much slower process, the deposit of coagulable lymph encroached on the edges of the remaining ring of nævus, which in the space of one month had become reduced to one-third its original breadth.

At this period it was thought right, in order to accelerate the process of obliteration, to repeat the operation. But on examination, the process of obliteration of the ring of nævus was going on so beautifully that we determined to leave it for daily observation.

The deposit of coagulable lymph, with obliteration of the vessels, gradually

encroached upon the breadth of the ring of nævus, and destroyed its redness and tumor. Each successive week induced an obvious change. The whole process was so distinct, and so peculiar, that, however a shade of doubt might be cast upon the former case, none could possibly subsist in regard to the nature of the cure in this.

That every kind of vascular nævus, and even some tumors, morbid growths, and ulcers, may be cured by this simple operation, I have no doubt. A mode of obliterating vascular texture, and of changing vascular action, must have numerous applications in surgery. I have thought it, therefore, incumbent upon me once more to draw the attention of the profession to this subject.

14, Manchester-Square,
Dec. 6th, 1831.

DR. CAMPBELL ON PUERPERAL
FEVER.

*To the Editor of the London Medical
Gazette.*

SIR,

I AM desired by Dr. Campbell, of Edinburgh, the author of one of the most valuable works we possess on Puerperal Fever, to communicate to you the following letter for publication, which was addressed to me in the month of May last.—I am, sir,

Your obedient servant,
ROBERT LEE.

14, Golden-Square,
Nov. 15, 1831.

Edinburgh, 4, Picardy-Place,
May 26, 1831.

My Dear Sir,—Your obliging communication of the 17th April reached me only two days since, and from this unaccountable delay I fear you may not receive my reply in time to enable you to make any use of it.

My experience in the disease, which has of late engaged so much of your attention, has not been very extensive since the publication of my work on the subject; and of many such cases as have fallen under my notice, I am ashamed to acknowledge, that I have not preserved detailed records. Since

the close of 1822, the patients I have seen have not exceeded thirty in number: of these many died, and in most of them the examination of the body was obtained. In far the greater number, the peritonæum, generally including the uterine reflections, presented decided marks of inflammation. Both the ovaries, in most instances, were either simply enlarged or much disorganized. Though I observed that the uterus generally participated in the morbid changes, and in a few instances to a great extent, yet it was rarely so much affected, either in its external tunic or substance, as other parts of its investing membrane. In one instance only I have seen uterine phlebitis, though I have for several years past particularly attended to this point. This last was a case in which, as was obvious on dissection, injury had been done to the uterus by the medical attendant, in rectifying some malposition of the fœtus. The woman died early on the sixth day after delivery, and in four days and six hours from the commencement of rigors. Four days after her decease, the infant (a female) died of erysipelas and abdominal inflammation.

On the question of infection, I am as much as ever impressed with the belief, that unless the practitioner has been engaged in the dissection of the bodies of those who have fallen victims, the disease cannot be conveyed by him, from females labouring under it, to others recently delivered; but, if he has been so engaged, I have strong reasons for believing, that he may be the means of propagating it. In October 1821, I assisted at the dissection of a woman who died of the disease, after an abortion of the early months; the pelvic viscera, with the external coats, were removed, and I carried them in my pocket to the class-room. The same evening, without changing my clothes, I attended the delivery of a poor woman in the Canongate; she died: next morning, I went, in the same clothes, to assist some of my pupils, who were engaged with a woman in Bridewell, whom I delivered with forceps; she died: and of many others, who were seized with the disease, within a few weeks, three others shared the same fate in succession. Dr. James Orr, a discerning and judicious practitioner, who is now established at Belfast, as-

sisted me at the time. In June 1823, I assisted some of my pupils at the dissection of an unmarried female, who died of the disease at Canon-mills, after delivery with forceps. For want of accommodation, I was unable to wash my hands with that care which I ought to have done: on my arrival home, finding that two patients required assistance, I went to attend them without further ablution of my hands, or changing my clothes, and both of them were seized with the disease, and died. Since this last occasion, I have almost always allowed such dissections to be conducted by gentlemen who were not afterwards likely to be engaged with women in child-bed. For the last two years, I have scrupulously avoided, by *actual contact*, assisting at such post-mortem examinations; and although I have witnessed three, if not four dissections of the disease, and that it has been rather prevalent here during that period, yet I have not in any instance been able to trace its migration from the quarters where those examinations took place, to any part where either my pupils or myself were afterwards in attendance. My notions regarding the treatment are before the public, and I have little more to add on that head. Such patients as I have seen recover, were certainly indebted for the happy result to venesection; but my belief is, that there are some cases in which no sort of treatment can be of any avail, even when the disease is early attacked. In three cases, an enema, composed of lb. j. of warm gruel, and ℥ij. ol. tereb. vol., almost instantaneously relieved the *termina* and *tenesmus* under which the patients laboured; and were followed by copious, bloody, mucous dejections, and recovery. You are at liberty to make what use you please of the foregoing statement, or any part of it.

With many thanks, believe me, my dear sir,

Very sincerely yours,

WM. CAMPBELL.

COMPOSITION OF CINCHONA.

To the Editor of the London Medical Gazette.

SIR,

I REQUEST the favour of the insertion in your journal of the following notice on *Cinchona Cordifolia*.

The constituents of the *cinchona cordifolia* are ascertained by analysis to be—

1st, A free acid, easily disengaged by distilled water; 2d, quinine, obtained by neutralizing the acid No. 1 with magnesia; 3d, quinine independent of that which is in combination with the acid No. 1; 4th, bitter extractive; 5th, resin; 6th, gummy matter; 7th, gluten; 8th, tannin, combined with gallic acid; 9th, colouring matter; 10th, muriate of soda; 11th, sulphate of soda; 12th, iron; 13th, woody fibre.

Quinine is a bitter substance of the bark, forming characteristic salts with acids, and not containing any of the principles from No. 4 to 13; it appears to be an elementary substance.

In the preparation of the *liquor cinchonæ cordifoliæ*, it has been attempted to combine all the efficient properties of the bark (excluding Nos 6, 7, and 13, in which no active principle can be discovered), and it is presumed that the object has been effected in that preparation.

The *sulphate of quinine* can only be partially efficient as a medicine, in consequence of the absence of all the properties above mentioned (from No. 4 to 13); and the decided superiority of the *liquor cinchonæ*, as a medicine, being fully admitted by many competent judges, it appears to me to be of importance to place that preparation under the attention of the profession at large.

I have the honour to be, sir,

Your obedient servant,

R. BATTLEY.

Ophthalmic Laboratory, Moorfields,
Nov. 15, 1831.

VARIETIES OF MAGNESIA.

To the Editor of the London Medical Gazette.

SIR,

IN the Medical Gazette of August 13th, 1831, is a case of poisoning by sulphu-

ric acid, by Martin Sinclair, M.D. Fellow of the Royal College of Surgeons of Edinburgh.

I request your insertion of a few remarks suggested by the following passage in the account, (vide Med. Gazette, Aug. 13th, 1831, page 625, first column.) The passage is as follows:—“By medical writers the carbonate of magnesia is recommended in preference to the carbonate of lime, and is certainly superior, by producing a saline aperient by combining with the sulphuric acid. In the present case, however, the carbonate of lime was preferred as having a greater affinity for sulphuric acid, and because being more easily missible with liquids, it could be administered in greater quantity in a short space of time.” This latter clause would indicate that the writer was acquainted only with the ordinary carbonate of magnesia of commerce, prepared from the residuary liquor of sea-water, after the extraction of common salt. This is light, mixes imperfectly with water, and occupies a large bulk even when mixed; it has a taste which, though not very readily discoverable on placing a small quantity on the tongue, is to many very disagreeable in a copious draught. This taste appears to depend in some degree on the presence of chlorides and sulphates of magnesia, lime, and soda, left behind in the process of washing the carbonate of magnesia. But since the nauseous flavour of sea-water is chiefly owing to dissolved animal and vegetable matters, and is scarcely perceived in water taken up at a great distance from any shore, I know from experiment so much of the readiness with which soluble, animal, and vegetable substances unite with and adhere to all the common earths, (I waive the question of a real combination) that I should expect this flavouring matter, too minute and subtle, perhaps, to be at present detected by our chemical tests, to adhere to, and be precipitated with the carbonate of magnesia, rather than to remain dissolved, and be washed away. Certain it is that I do not find on analysis of light carbonate of magnesia so large a portion of muriates or sulphates as fully to account for its disagreeable flavour. But there is another carbonate of magnesia to be met with in trade which I have been in the habit of recommending and supplying, and which is approved, I believe, by all who have tried it: this is known

as pure, or heavy carbonate of magnesia.

An ounce measure, lightly filled, weighs about 160 grains; of the common sort, the same bulk weighs 48 grains. This heavy carbonate is free from taste; it is not prepared, in any stage, from sea-water, but from solution of sulphate of magnesia, free from lime, from muriates, and from vegetable bitter. There is another somewhat curious reason of trade for its closer approach to purity. Carbonate of magnesia, when first precipitated, is very light, and of course much mixed with the solution of the alkaline precipitant. Repeated washing, while it carries off the alkaline salt, breaks down that crystalline structure on which the lightness depends, and leaves it heavy. A few, and but a few generations back, carbonate of magnesia was many times its present price, so as to be worth adulterating with carbonate of lime; and, moreover, that ready and infallible test for chalk in such a mixture, its not dissolving entirely in moderately diluted sulphuric acid, was unknown, or in few hands.

Medical practitioners had then no easy way of judging of its freedom from adulteration with chalk but from its extreme lightness, and to procure it light rather than tasteless, was the great desideratum of the laboratory.

Neither the spread of chemical knowledge, nor the example of Dr. Henry's superior preparation, has entirely abolished this prejudice, and hence the manufacturers of common carbonate of magnesia have a strong motive to wash slightly, in order to preserve that lightness which is now a real defect without a countervailing advantage. The manufacturers of pure, heavy carbonate of magnesia, who do not aim at lightness, have not this motive to spare washing, and their preparation is as much distinguished by mixing readily with liquids, and by freedom from taste, as it is by chemical purity. I think no one accustomed to its use could write, "carbonate of lime was preferred because more easily missible with liquids;" it is actually less so.

Two things I wish to guard against; first, the being supposed to possess any nostrum in magnesia, or to claim the exclusive source of supply for the heavy carbonate, or the calcined magnesia from it, although, in my own con-

nexion amongst apothecaries, I am in the habit of furnishing them largely with this magnesia.

Next, the appearance of imputing any blame to the medical practitioner who treated the case. He seems to have acted with zeal and promptitude, and the same termination might have taken place under any other management; but I beg leave to point out a circumstance forming a reason for preferring magnesia, or its carbonate, to chalk, which he has not noticed, whether aware of it or not, and which in other cases is quite likely to make all the difference between *life* and *death*. It is, that from the comparative insolubility of sulphate of lime, when chalk is added to dilute sulphuric acid, however large the quantity of either, the action of the sulphuric acid on the carbonate, and its saturation with lime, soon stop, from the first portions of sulphate forming a crust round the carbonate, protecting it from the further action of the acid. Even agitation, without actual crushing, is insufficient to bring the whole of the carbonate of lime within the sphere of action of the sulphuric acid. There may exist together, therefore, in the stomach a great mass of carbonate of lime, enveloped and protected by sulphate of lime, and at the same time a large quantity of sulphuric acid, either kept wholly separate from, or very slowly acting on, the chalk, but exerting the full force of its deadly energies, chemical and physiological, on the structure or functions of the stomach, without check or controul. With magnesia this cannot possibly be the case. I should recommend as the best preparation in every such case, if at hand, Henry's calcined magnesia, or the pure calcined magnesia obtained by calcining the carbonate above described, on account of avoiding distressing efforts at eructation in the corroded state of the œsophagus and surrounding parts. Next to these, pure heavy carbonate of magnesia, or even supercarbonate of soda, and chalk only as a temporary substitute, in cases occurring in the country, where chalk might be in the house, and a mixture could be prepared and administered whilst a messenger was on the way to the nearest place where some variety of magnesia could be obtained.

WILLIAM WEST.

Leeds, 31st of 10th month, 1831.

DR. STEVENS'S ACCURACY QUESTIONED.

To the Editor of the London Medical Gazette.

Suffolk-Place, Pall-Mall,
5th Dec. 1831.

SIR,

ANXIOUS that no misconception or misinterpretation of my statement in the Westminster Society, relative to Dr. Stevens, may go forth to the public, I solicit a corner in the next number of your journal for the following remarks.

A few weeks ago, I received a rather voluminous document, with enclosures, from Dr. Hackett, chief medical officer at Trinidad, charging Dr. Stevens with misrepresentation of facts, as they occurred at Trinidad, and as they formed certain data for his doctrine and treatment of fevers; also of garbling, to suit his purpose, a letter from Mr. Greatrix, relative to the alkaline treatment of yellow fever. These and other grave charges were, in my mind, calculated to do injury, or even disgrace, to the medical profession, and, without perusing any more of the document, I laid it aside, determined not to make it public. But my attention being roused by the announcement of Dr. O'Shaughnessy's paper, and more especially by the very strong terms in which Dr. Stevens's discoveries were spoken of in the Medical Gazette, in which it is stated that Dr. Prout considered these discoveries as of the last importance to mankind, I felt that it would be culpable, if not criminal in me, to withhold from the profession the counterstatements of the army medical officers of Trinidad, from which it appears that soda had nothing whatever to do with the success of the treatment in the above island; that the blood of *sodafied* patients, after death, was found to be precisely similar to that of the *unsodafied*; and lastly, that the changes, real or apparent, produced by the admixture of soda with blood, out of the body, could be produced, without any soda at all, simply by putting the patient into a hot bath, and bleeding him in the bath.

On perusing the whole of the document, I am happy to say that it contains the most important mass of information, both pathological and therapeutical, which has been laid before the public for many years, and that it brings forward views which may tend to elucidate

the nature and treatment of the reigning epidemic. On this account I shall publish the document forthwith, leaving Dr. Stevens to justify his conduct and support his hypothesis in the best way he can.—I am, sir,

Your most obedient servant,
JAMES JOHNSON.

EXPERIMENTS ON THE BLOOD.

To the Editor of the London Medical Gazette.

SIR,

THE notices repeatedly inserted in the Medical Gazette, of certain opinions advanced by Dr. Stevens, regarding the effects of some of the neutral salts on the blood, have naturally directed attention to this point, at a time when the failure of all ordinary methods of treatment in cholera has almost unavoidably led practitioners to inquire, whether there be any yet untried expedient which might by possibility be useful. About a month ago, having procured successive supplies of newly-drawn blood, I mixed it with different substances, obtaining the well-known general result, of rendering the fluid dark and thick by means of strong acids, and of a bright scarlet by means of the neutral salts. The transition from the modena hue of venous, to a vermilion *resembling* that of arterial blood, is certainly a remarkable phenomenon, and those present agreed, that if any thing was to be hoped for from effecting a similar change in urgent cases of cholera, it was most rationally to be attempted by direct injection into the veins—a process which Mr. Arnott undertook to perform, should circumstances occur to render the proceeding feasible. Meantime, however, reflecting that the change of colour had been most conspicuously produced by a salt (muriate of soda) containing oxygen, in a state of combination (with sodium) in which it was next to impossible it should be separated, I very much doubted whether any thing like oxygenation took place, and this idea was farther strengthened by recollecting, that though nitrate of potass contained abundance of the principle in question, in a state readily separable, yet the salt passed through the circulation unchanged, was eliminated

by the kidneys, and might be obtained from the urine, still as nitrate of potass. Under these circumstances, the only rational conjecture which presented itself to my mind was, that the change of colour was effected by some process not involving the decomposition of the salts, but analogous to the phenomenon displayed by acids, in reddening the blue vegetable infusions. In this dilemma, I applied to Dr. Prout, in the hope of obtaining from him some additional light upon the subject; but he informed me explicitly, that though long engaged in investigating the effects of different agents on the blood, he had not been able to satisfy himself as to the manner in which the change alluded to was effected. Thinking there was little chance of my finding out what the first of our organic chemists had failed to discover, but still desirous of making some advance towards ascertaining whether the salts would act in any degree as a substitute for the arterialization of the blood, I tried the following experiment upon rabbits:—The windpipe was compressed till the animal was rendered insensible by the circulation of black blood, after which, and while the heart still continued to act, solutions of muriate of soda and of nitrate of potass, of various strengths, were injected into the jugular vein. In no case did any degree of resuscitation, however short or trivial, indicate that any influence was produced by the injection; nor did the heart act longer where the injection was fairly thrown in, and where by examination afterwards the blood was found to have been reddened by it, than in another case where the pipe had slipped from the vein, and the solution passed merely into the adjacent cellular texture.

In another instance, a solution of nitrate of potass was injected into the carotid artery, so as to make it pass at once to the brain, and the animal recovered, but it was found that respiration had been too imperfectly interrupted to render the experiment at all satisfactory, and I have had no opportunity of repeating it.

I admit readily that these observations and experiments are not sufficient to warrant any positive inference, and that the subject is deserving of investigation, but so far as they go, they are not calculated to strengthen our hopes

of benefit from the suggestion contained in your last number.

My reason for giving publicity to any remarks so imperfect is, that I wish it to be understood exactly to what extent I have offered any opinion. The *Morning Post* has erroneously identified me with all that has been said in the *Medical Gazette*, but this is at once an honour and a responsibility which, not being due to me, I must decline. When, at a recent public meeting, the *Medical Gazette* was accused of endeavouring to take the credit which belonged to another, I was enabled to contradict the statement, seeing that my own attention had been particularly directed to the subject in consequence of what had previously appeared in the pages of that journal.—I am, sir,

Your obedient servant,

R. MACLEOD.

Henrietta-Street, Cavendish-Square,
December, 5, 1831.

MORINDA CITRIFOLIA.

THERE are two species of *Morinda*, the *umbellata* and *citrifolia* (small and large leaved), which are found indigenous and abundant among the islands forming the eastern Archipelago, where they are used as props for the pepper-vines, or planted as a shade for the coffee-plants, and is named by the natives *Mangkudn* *. The roots of the first are only mentioned as being used as a dyeing material in the eastern Archipelago. The *Morinda* is indigenous also to the Philippine Islands, where it is named in the Tagalo *Tambungaso*. The natives of these islands, when a limb is fractured, use the leaves of this shrub, anointed with oil, to lay over the surface of the fractured limb; and it is considered by them of benefit in allaying the inflammatory action.

This shrub attains the height of ten or twelve feet. At Tahiti, and most of the Polynesian islands, where it is also found indigenous, the inner bark of the root is used for dyeing the native cloth of a fine yellow colour: this is done by infusing the bark in water, into which

* In the languages of the western countries of the Archipelago, the tree is named according to the idiom of the pronunciation of the people, *Mangkudu*, *Bangkudu*, or *Wangkudu*; the three initial consonants in these cases being commutable and very arbitrarily used.—*Crawford's Indian Archipelago*.

the cloth intended to be dyed is afterwards placed, and being suffered to remain for some hours, is taken out and dried in the sun. At Tahiti the shrub is called Nono, or Aari; at the Sandwich Islands it is called Noni. The fruit is eaten at some of the Polynesian Islands, in seasons of scarcity.—*Mr. G. Bennett's MS. Journal on Polynesia, &c.* 1829-30.

THE MAMI TREE (ANTIARIS) OF
THE ISLAND OF TUCOPIA, SOUTH-
THERN PACIFIC OCEAN.

Natural Order, *Urticæ inter Brosimum et
Olnediam.*

Class, *Monocia*.—Order, *Tetrandria*.

DURING a brief visit to the Island of Tucopia, on the 7th of May (1830), I observed this tree planted in rows, near the native dwellings, but whether it was indigenous to the island I could not correctly ascertain. It is allied to the far-famed Upas-tree of Java, and seems to accord with the *Antiaris macrophylla* described and figured by Mr. Brown, in the Appendix to Flindel's Voyage, vol. ii. p. 603*. It is called Mami by the natives.

The tree is of slender growth, with pendulous branches. I have seen it growing to the height of eight and twelve feet; the leaves are oblong, large, pointed, distinctly veined, and of a light green colour; the fruit is oval, rather longer than a pigeon's egg, rough externally, and of a beautiful crimson colour. On making a section of the fruit, between the husk and kernel is a quantity of white viscid juice; the kernel, of a white colour and intensely bitter taste, is enclosed in a thin shell, of a greyish colour. It is used by the natives either in dyeing or manufacturing their native cloth, but which I could not, from my short stay, exactly ascertain.—*Mr. G. Bennett's MS. Journal on Polynesia, &c.*

* He describes it as "a shrub, or very small tree, observed in stony places, on the shores of the Company's Islands, adjacent to Arnhem's Land, on the north coast of New Holland, in about 12 degrees S. latitude, bearing both flowers and ripe fruit in February 1803."

SPONTANEOUS COMBUSTION.

On the 23d of March, 1830, when at the island of Rótuma, Southern Pacific Ocean, I had requested a native to bring me some of the sweet-scented male flowers of the Pauhuf (*Pandanus odorotissimus*); they were accordingly brought on board, enveloped in native cloth, and packed in baskets formed of the cocoa-nut frond; and having been brought off to the ship during a heavy sea, were wetted by the spray. I laid them aside unopened in my cabin. Some hours after, looking at them I observed a steam arising from the basket; and, on taking them out, found that a spontaneous combustion had taken place among those situated underneath, most of which had become completely blackened, and the heat which proceeded from them was very great. Had they been incautiously stowed in a ship's hold, the consequences might have been very serious.—*Mr. G. Bennett's MS. Journal, 1830.*

LUMINOSITY OF CORAL INSECTS.

On the 20th of March, 1830, when coming off to the ship at Thor Bay, island of Rótuma (Southern Pacific Ocean), some hours after dark, a long reef of coral extended some distance from the beach, some part of which was dry at low water, and at other places the water was very shallow. The canoe in which I was going off grazed with some degree of violence on the coral nearly at the termination of the reef, when the surface of the water immediately became brilliantly phosphorescent, and remained so for a brief period. The water at other places I did not observe, this night, displaying any phosphorescent light: can we infer from this that the coral zoophytes have luminous properties? — *Mr. G. Bennett's MS. Journal.*

THE SUGAR CANE—(SACCHARUM
OFFICINARUM.)

THIS valuable cane is indigenous to South America, Persia, East Indies,

China, and the Polynesian Islands, and of it there are several varieties. At Polynesia, as in the Eastern Archipelago, it is only cultivated by the natives for eating in a raw state. Sir Stamford Raffles states, that in Java they have eight varieties, and the sugar cane is designated by the name Tebu, both at that island and throughout the Polynesian Archipelago. Among the varieties at Java, the dark purple cane, "which displays the 'greatest luxuriance, and shoots to the length of ten feet, is the most highly prized;" the Javans, as well as the Polynesians, are unacquainted with any artificial mode of expressing the saccharine juice and granulating it. Among the Polynesian Islands I have seen it attain a larger circumference, and a greater length of eatable cane (from ten to twelve feet), at the Sandwich Islands and Tahiti, than at any of the others. At Tahiti Mr. Bicknell, and Mr. S. P. Henry, manufacture sugar from the canes, and the quality is most excellent. At the Society and Sandwich Islands, Rótuma, Tongatabu, New Hebrides Group, &c. I observed several varieties, differing in the colour and quality of the stalk, and in a very slight degree also in the leaves.—*Mr. G. Bennett's MS. Journal on Polynesia, &c.*, 1829-30.

ANALYSES & NOTICES OF BOOKS.

L'Auteur se tue à allonger ce que le lecteur se tue à abréger.—D'ALEMBERT.

An Essay on the Epidemic Cholera of India. By REGINALD ORTON, Surgeon H. P., late of his Majesty's 34th Regiment of Foot. Second Edition, with a Supplement. 8vo. pp. 488.

It would be occupying the pages of our journal with matter already familiar to our readers, were we to enter into minute details regarding the history and symptoms of cholera. Had the work before us presented itself sooner to our notice, we should have borrowed largely from its pages, as containing upon the whole the most complete account of the disease which has yet been offered to the public. But though we must thus pass by much of its contents without notice,

there remains behind a large portion of highly-interesting discussion, contained in an extensive supplement and appendix. In these some of the opinions contained in the first part, which has scarcely been altered from the former edition, are considerably modified—particularly that regarding contagion; the accumulation of evidence having produced on the mind of Mr. Orton the same conviction which must, sooner or later, be admitted by every unprejudiced person—namely, that though the assumption that the disease is transmitted from man to man is not without some difficulties, yet these are "as dust in the balance," compared to those which present themselves if we adopt the opposite hypothesis.

In the supplement we find the opinions of the writer thrown into the form of propositions; and the first of these relates to the contagiousness of the disease, concerning which the inferences are—1st, that it is conveyed either mediately, or immediately, from man to man; 2d, that the virus is very subtle, or volatile, and is readily conveyed by the atmosphere, whence it happens that there is little, if any, increase of danger from the most intimate communication with the sick, above what attends the common intercourse of society; 3d, that the period during which the poison lies dormant is generally very short, and sometimes imperceptible, though at other times it is more protracted. A full account of the chief points tending to prove the contagious nature of cholera having recently appeared in this journal, we do not think it necessary to go over the ground again, but can confidently refer those desirous of farther information to the lucid observations of Mr. Orton.

This brings us to the second section, treating of the influence of the seasons and states of atmosphere on the disease, on which subject the propositions laid down are as follow:—

"Great irregularity and intemperature of the seasons has preceded and attended the rise and first spread of the epidemic over India.

"The disease has prevailed in India chiefly during that half of the year when the sun was on the same side of the equator.

"A high atmospheric temperature is a great cause of the disease.

"A condition of the atmosphere

indicated by the formation of thick clouds, heavy rain, and storms (particularly thunder-storms), or the immediate approach of these phenomena, is a great cause of the disease."

Mr. Orton, in commenting on the preceding positions, alludes to the opinions of various writers who have taken a different view of the subject; and certainly not a few, both at home and abroad, have been opposed to him on this point. He observes, however, that a high atmospheric temperature, especially in connexion with heavy rains, is acknowledged to be a principal cause of that form of cholera which prevails in Europe, to which the sporadic cholera of India is closely allied—so closely that, according to Mr. Orton, in the symptoms no distinction can be drawn between them; and he goes on to shew, by reference to numerous Indian reports, that similar states of atmosphere generally attended the most severe visitations of cholera; and we must say, that he adduces some very remarkable facts, particularly as regards the immense quantity of rain which fell in some places.

"Such and so striking (says our author) being the circumstances attending the rise of the malady, and its first and principal ravages all over Lower Bengal, we may fairly infer that it was owing to this exaltation of the common causes of the endemic or sporadic disease that it took on the epidemic and contagious form, and thus became capable of diffusing itself far and wide over the earth."

The influence of season is farther shewn by a reference to the calculations of Mr. Jameson, as to the appearance of the disease in separate camps during the different months of the year; and these being thrown into a tabular form, stand thus:—

January.....	1
February	5
March	10
April	18
May	23
June	14
July	10
August	22
September.....	16
October.....	7
Novembsr.	5
December	0

From March to September, the number of irruptions of cholera, 103; whilst
210.—IX.

in the other half-year it is only 26; and during the months of December, January, and February, or half the latter period, the number is only 4. The author establishes a clear line of distinction between the first and subsequent visitations of the disease. In the first it prevails among masses, many of whom are susceptible, and carries off great numbers; but afterwards, the "original stock of susceptibility" having been exhausted, the contagion only lurks among the people, to become developed when the atmospheric condition is peculiarly favourable.

The third section is devoted to the discussion of the proposition, that "troops on their march from station to station, or in the field, and persons travelling in India, are particularly subject to the disease;" and the evidence adduced in illustration of it is such as must convince any one who takes the trouble to peruse it.

Section fourth brings us to the influence of localities on the prevalence of the epidemic; and the propositions regarding this point are as follow:—

"PROPOSITION.—The disease shews an evident preference for the low and level parts of a country, and avoidance of more elevated tracts.

"It is found to prevail most severely in all the moist, close, and filthy parts of any city or neighbourhood.

"It commonly follows the course of rivers, both navigable and unnavigable.

"It prevails most severely in all those countries and places where, from the prevalence of the endemic fever, malaria is known to exist; and in such situations its epidemic duration has commonly been protracted."

It appears to have been on the first spreading of the epidemic that the exemption of particular situations was most remarkable; for, in its subsequent visitations, it generally reached the places it had previously left untouched; and in some instances, on its second journey, if we may so speak, it visited those places only which had previously escaped. This, however, was not the fact generally. On most of these occasions it would appear that the disease displayed a greater degree of malignity than at first, attacking those who had before seemed unsusceptible of its influence. High situations are undoubtedly, as a general rule, less subject

to cholera than those which are low; and dry spots are more exempt than damp; while in any locality a dull, moist, hot state of atmosphere is more favourable to its development and ravages, than one which is cool and clear. It seems never to have reached the interesting plateau constituted by the Neelgherry mountains, though it prevailed extensively in the country bordering upon them. Where fevers were endemic, cholera was sure to prove severe, especially on the banks of swampy rivers, a fact attributed by our author to two causes—"human intercourse and malaria."

The fifth section relates to the prevalence of other diseases in connexion with that of cholera; and the proposition is,

"The extensive prevalence of various other endemic or epidemic diseases, particularly the malaria fevers, has often accompanied or immediately preceded or followed that of the epidemic cholera."

It appears that in 1816, being the year before cholera broke out in Bengal, there was an extraordinary prevalence of remittent fever, and likewise of an "infectious malignancy nanche;" while, on the other side of the peninsula, on the coast of Kutch, the plague made its appearance, and spread to a considerable extent. Besides these unusual visitations, it seems clearly proved by the evidence before us, that the common diseases of the country were increased in prevalence during the existence of cholera. In some instances the epidemic soon passed into very severe remittent fever, of which the patients sometimes died "almost instantaneously, with every symptom of apoplexy." All this goes far to prove, that there exists a peculiar state of atmosphere, which facilitates the development of cholera, and aggravates its violence; and farther, that this epidemic atmospheric peculiarity likewise occasions or favours the irruption of various other diseases.

Section sixth treats of susceptibility to the disease, and of its exciting causes, giving rise to these inferences:—

"In every body of people there is a large proportion incapable of receiving the disease, though exposed to all its usual causes.

"Having undergone an attack of the disease confers a great de-

gree of immunity, at least for a time, from its future attacks.

"The indigent part of society, the old, the weakly, or unhealthy, and the intemperate, are particularly liable to the disease.

"The usual exciting causes of the disease are exposure to great heat, cold, or moisture, errors of diet, over exertion, the depressing passions, and in general whatever tends to debilitate or disorder the frame."

In India, not less remarkably than in Europe, has the disease been especially prevalent among the lower classes of society—the ill-fed, ill-lodged, and dissipated; and, taken altogether, the proportion of persons susceptible of the malady is small in comparison to those who fall under the influence of other epidemics, as plague, or yellow fever. It is, however, very difficult to say on what peculiar condition of the system the susceptibility depends; for while some, such as those above alluded to, are obvious, there seem to be others entirely hid.

"How often (says Mr. Orton) have we seen persons of the most robust and healthy habit, and the last whom we should expect to be obnoxious to cholera, seized by it, even when it was not prevailing to any considerable degree, in its very worst forms! Doubtless the disease found in them some congenial diathesis, some hidden flaw in the constitution, by which it was enabled to make its fatal invasion."

Section the seventh and last, consists of a comparison between the Indian and European cholera. Their identity is admitted, but considerable difference is held to exist with respect to the febrile state which follows the first stage of the disease in Europe. To this circumstance Mr. Orton is inclined, and we think with much justice, from the greater development which has occurred of the contagious principle, and the power evinced by the disease of resisting cold—a power which it has apparently acquired since it entered Russia. The extraordinary prevalence of sporadic cholera all over England is particularly alluded to, as shewing a peculiar state of atmosphere; and the valuable Reports of Dr. Burne, published in this journal, July 2d, are especially referred to, in corroboration of our author's views as to the relation-

ship between English and Indian cholera. It is curious, too, that Mr. Orton fixes upon Sunderland as a place likely to display the more virulent form of the disease, although the opinion must have been written some weeks before its actual irruption.

"I have also (says our author) the authority, *vivâ voce*, of Dr. Clanny, for the most unusual prevalence and malignancy of cholera at Sunderland during the present autumn. It is greatly to be feared that these are but the skirts of the approaching shower. This unusual prevalence of common cholera remarkably accords with the same fact, as already stated, occurring on the peninsula of India the year before the epidemic reached it, and when Bengal was actually suffering its ravages."

We must here close our short account, or rather our notice, of Mr. Orton's valuable work: to give a faithful digest of its contents would require several entire numbers of our journal. Every medical man desirous of making himself well acquainted with the all-engrossing subject of which it treats, ought to have the volume in his possession; and we trust we have said enough to induce them to study its contents.

MEDICAL GAZETTE.

Saturday, December 10, 1831.

"*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"—CICERO.

WHAT OUGHT THE ANATOMISTS TO DO ?

NEVER, we believe, since anatomy was first cultivated in this country were the teachers of it reduced to such awkward extremities as at present. Shackled with a weight of responsibility from the obligations entered into with their pupils, they cannot possibly throw up their business, much less can they adopt the rash expedient (which we are sorry to hear has been in actual contemplation)

of calling on government to close their schools—while a mass of difficulties arising from the spirit of surveillance, which has been awakened by the disclosure of the recent atrocities, and from the unusual degree of odium attaching to their profession in consequence, must not only interfere to prevent the fulfilment of their engagements, but serve to drive them almost to desperation. In this painful predicament they, of course, must look round them to see what is best to be done: and we can very well imagine the anxiety with which they turn from public feeling to the press, and from the press to the prospect of parliamentary relief. From public feeling, we fear, they have nothing to expect: if the schoolmaster has been abroad, here at least he has not done his duty; and little or none has been the improvement which has taken place among his precious dogged-headed slow-to-be-moved scholars. It may be that much of this is owing to the faithless stipendiaries to whom, in his multifarious employments, he commits the task of the public enlightenment on the usefulness of anatomy; but we can tell him that it is a task, of which it were worthy of all his own best exertions, to attempt the accomplishment. Surely the people of this country, if they were to be judged by the progress which right notions regarding the nature of anatomical pursuits, have made amongst them, must be accounted the most backward and obstinate people in Europe. We know that they have been encouraged and complimented ever and anon for this perverse adherence to old prejudice by certain self-constituted masters of morals among them; but the *opiniâtreté* of the vast majority is too deeply-rooted, and too wilful, to be influenced one way or other by the fulsome few who would pretend to direct it, and at the same time presume to inculcate a spirit of opposition to one of the most

useful of sciences. The British vulgar, in short—including in that denomination some of the very highest as well as the mass of the very lowest persons in the community—are doomed, we fear, to be more slowly convinced of the advantages flowing from the advancement of knowledge in this branch, than in any other. Facts for the last few years have most remarkably evinced the truth of our assertion; and therefore is it that we feel ourselves deliberately bound to repeat that the friends of anatomy have little, if any thing, to hope from improvement effected in that quarter.

The prospect, however, is better when we look to the press. This great engine for working out the destiny of nations, has, we rejoice to think, undergone a thorough amelioration of sentiment with regard to the question of anatomy; and unsanguine as we are respecting the impracticable materials on which it has in the present instance to operate, all our hope is entirely rested upon it. We have seen the day, and we are not so very much older now than we were then, when the leading journals of Great Britain, with but few exceptions, were up in arms on the least mention of a bill for the regulation of the schools. The case is now materially altered. Circumstances, some of them of an appalling character, have occurred during the interval, and have had their due weight, along with time, “the greatest of innovators,” in effecting this most desirable change. The result is certainly promising. There is, to be sure, much warning, much advice, tendered by the press to the advocates of dissection; but there is also much consolation held out—and above all, there is a certain degree of good feeling and earnestness abundantly displayed.

But the tribunal which must determine the question in the last resort is centred in the collective wisdom. What change, if any, has been effected in the removing

of prejudices in this quarter, it is difficult for us to say: but we should hope, that in the event of a simple, straightforward legislative measure being proposed for the consideration of parliament, no serious obstacles, as on a former occasion, may supervene. Our fears, however, must not be dissembled;—it is in the upper house, we apprehend, that all the difficulty of legislating on the subject will lie; and it ought never to be forgotten, that Mr. Warburton’s bill, such as it was, (and any thing, heaven knows, would be better than the present anomalies,) received its finishing *coup* in that house: it became necessary, as our readers will recollect, to withdraw it, in consequence of the determined hostility of a large number of peers, and nearly all the bishops—a curious instance, by the way, of the occasional approximation of the feeling and intelligence of the extremes of society.

As matters stand, most assuredly no respectable body in the community have more to complain of than the teachers of anatomy; and, perhaps, with the exception of their actual grievances, nothing can be more galling to them than the pretended remedies proposed by their ill-judging friends. “We think we know a way,” says one, “to reconcile the safety of the people from murder, with the regulated prosecution of the science of anatomy. Let the schools be *licensed*, and let one condition of the license be, to keep an *exact register* of every subject, describing exactly its age, colour, complexion, &c. by which it may be best identified, as well as the stage of its progress to decay—inserting dates, *even to the hour*. Then the schools must be open to the familiar visitation of two intelligent *inspectors*, who may examine the registers, and the *subjects* too if necessary, and who may be in constant communication with the Home Secretary’s office. This would throw no dif-

feulty in the way of the anatomist (!), while it would completely obviate the burking system. Let us give an illustration of the working of the plan :—A person is missing ; his friends apply at Bow-Street ; the application is forwarded to the visiting commissioners ; they examine the registers, going back to the period from which the missing person was last seen. If he has been *murdered* (what ! though this notable plan was to obviate all murder ?), though it were years before, there stands the clue to evidence against the murderers : the servants of the school can be produced against the murderers, and will furnish more or less satisfactory proof. The existence of this system will be quickly made known to the resurrection-men ; and if, after they know it, they repeat the practices of Burke and Bishop, they must know that they are rushing into certain destruction." Will it be believed that this is seriously put forth by one of the "best possible public instructors," as a certain remedy for the present untoward state of dissecting establishments, and actually wound up to a conclusion without telling how or whence the supply of bodies is to be procured. Yes, true, there are *resurrection-men* mentioned in the scheme. The dealing with these worthies, then, is to be connived at, while an exact account of their proceedings is kept in the register ; the school is to be turned into a sort of *morgue*, and a complete trap for the Burkers ! Excellent legislator ! while not one hint is thrown out of allowing the body-snatchers even a little more latitude in their operations. Surely he thinks that these old hands at every desperate mischief will simply suffer themselves to be caught with chaff, and that they will deal freely with those whom they know to keep a regular "hue and cry" of their proceedings ; and surely he supposes, in his wisdom, that the gentlemen who keep

schools may be thus turned into a useful body of police, and will think themselves liberally dealt with by having the use of the bodies (for which they have paid enormous sums) for their pains. Rank stupidity ! Rather let the doors of the theatres of anatomy be closed for ever, and the *living* dissected "without remorse or dread," than the students of a liberal profession be found mean enough to submit to such a system of organized thief-catching. Away with such *friends* of anatomy !

Yet this man, we have no doubt, means well, or at least not unkindly, to the profession, and is a fair specimen of the well-disposed, who think that, what with the prejudices, and what with the host of difficulties which have to be dealt with, nothing better than this simple "way" can be suggested. We could give an instance of another, who, in his regular morning dose of swaggering nonsense about "human shambles," and the atrocities of anatomists (whom he really seems anxious to identify with the "Burkers"), mixes up such a quantity of ignorance along with what would otherwise seem deliberate insult to the profession, that the beverage is perfectly neutralized and harmless. But he is the only exception, that we know of, to the liberal feeling so generally manifested around him ; and as his only object seems to be to attract notoriety by his obstinate wrongheadedness, we shall leave him in his honourable singularity, and not gratify him by a word more exposure.

All this, however, only serves to set the oppression of the anatomists more conspicuously in view, while the remedy may, perhaps, be as much as ever darkly concealed from sight. Such is not unfrequently the case ; the means that are most obviously within our power are often the most likely to be overlooked ; and this must be our excuse for appa-

rently recommending such simple expedients as every one might seem to have thought of before.

Much will depend on the line of conduct now adopted by anatomists themselves; much on the proceedings of the Council of the College of Surgeons assembled for the special purpose of providing a remedy for the existing evils; much on the tone in which a measure of relief shall be brought before parliament; and every thing else must rest with the temper of the House of Lords. From the people, nothing is to be expected: they will abide, we presume, by the decision of their representatives.

The uncereemonious remedy to which we have already alluded, of appealing to the government, and demanding that all the schools of anatomy be suppressed throughout the kingdom, until they can be revived again upon a proper footing, would be a remedy with a vengeance. Let the friends of anatomy beware how they adopt this method of proceeding. It has too much the air of bravado and intimidation to be productive of the least benefit. But we cannot seriously think that any liberal-minded body of men would be capable of such absurdity. A simpler course lies open to them. All *they* can do is, to make a feeling statement of their grievances, accompanied by a calm expostulation, addressed to the higher powers, and if actually determined to add a sanction to their representations, let them threaten *obedience to the laws*.

As for the College, their line of proceeding is more clearly marked out. Let them pointedly express the difficulties under which the profession labours; let them show what measures are most likely to remove those difficulties; and let them, in fine, gently, yet firmly declare, that *they will examine no candidate for their diploma, until due provision has been made for the schools*.

With regard to the legislative measure most proper to be recommended,

we would be understood to speak with the greatest diffidence. We dread to think that the prejudices against deriving the supply of the schools from the class of the "unclaimed poor" are as deeply-rooted as ever: they would seem to be almost invincible: not open to the artillery of reason, but deeply entrenched in a national peculiarity of thinking. Should this prove to be unalterably the case, the only resource is evidently to be found in the supplies which the jails, penitentiaries, and houses of correction will afford. The sentence of murderers must remain unaltered, and the bodies of suicides must be turned to advantage:—though we fear in this instance also we may have prejudices to deal with, there seems to be a *national* principle engaged in this matter; and *suicide*, without benefitting the interests of science, may probably be claimed as a *privilege* by the better classes in our community.

Above all, let promptitude and energy be displayed in whatever steps are taken. Nearly three years have now elapsed since Mr. Warburton's bill was lost among the Lords. Nothing has since been done. Political engagements, and great national schemes in progress, have been pleaded in excuse for neglecting the interests of anatomy. Can they be longer pleaded, or may the provision of the schools be any longer put off with impunity?

—

MEETING OF ANATOMISTS.

SOME evenings ago a meeting of lecturers on anatomy was called together, in order to consider what steps they ought to take, in consequence of the recent events connected with the supply of subjects for dissection. A resolution, having for its object to address a petition to the Privy Council, praying that all the anatomical schools in the kingdom might instantly be closed, was agreed to, with, it is said, only one dis-

sentient voice; and a committee appointed to carry this design into effect. On the occasion alluded to, some of the principal teachers were absent, while others were taken by surprise; and another meeting having been convened two days after, the above rather precipitate resolution was negatived, some of those, on reflection, opposing it who had previously voted in its favour. It was decided that a committee should be appointed to wait upon the Secretary of State for the Home Department, to confer with him as to the measures which ought to be adopted in the present crisis.

ALLEGED DISCOVERY OF AN ANTIDOTE TO CHOLERA.

A WELL-KNOWN physician at Sunderland has written to the government, announcing the discovery on his part of a cure for cholera, and intimating his readiness to make it known on receiving an adequate compensation. Desirous as we are to express ourselves with moderation, we can scarcely restrain our indignation at the bare idea of any man stopping to make his real or supposed discovery a matter of trade and barter at the moment his fellow-creatures are dying around him; and such we have heard is also the sentiment contained in the cutting answer which has been sent to him. If the Doctor has made any discovery, let him follow the example of Jenner, by giving it to the world, and, if it prove successful, the country will not think any sum too large a recompense. But then it must be shewn that it really is a remedy, and, to do this, a very different rate of mortality from that which has hitherto prevailed, must be exhibited. Unless there be some explanation to be offered, such as we cannot at present anticipate, this event will be a crowning to the discreditable proceedings which have already taken place at Sunderland.

DR. JOHNSON AND HIS "CREED."

DR. JAMES JOHNSON, in the last number of the *Lancet*, says, "The editor of a contemporary journal has instituted a series of attacks on me, apparently for changing my creed; though he himself sets out with a declaration that he has entirely changed his own, from anti-contagion to contagion. I have not changed my creed; but *why* he changed his creed, is best known to himself." It would be affectation not to admit that we are the culprits here alluded to, and the significant "*why*" (in italics) would seem to imply that we had better or worse reasons than other people for having supposed, from the history of cholera in India, that it *was not* contagious, and believing, from its history in Europe, that it *is* contagious. If the querist can discover why Dr. Russell, Mr. Orton, and many others, have become contagionists, we shall not require to answer his question; the why and wherefore, as applied to them and to us, being, we presume, precisely the same. The writer goes on—"At present I shall not pursue this subject. I am not in the habit of making attacks on any man; but I will not hold myself bound to suffer the arrows of malevolence to fly about my head without repelling them." The "arrows of malevolence" flying about one's head, is a very pretty figure of speech, but the worthy Doctor is quite mistaken in supposing that such weapons were levelled at him by us; neither were our observations made, as he says, because he "changed his creed," but because he chose to address the public, through the medium of the daily press, in a series of papers, which we thought calculated to do harm. The opinions of any man who does this, become public property, and we have a right to deal with them as such. But why cannot our "ancient ally" have patience?—that same pursuing of the subject to which he alludes, and which is to appear in his next number, ought surely to content him. Though, it seems, our contemporary does not recommend the use of *common salt* in cholera, yet every one knows how largely he deals in *Attic salt* when he himself is choleric. Doubtless, the forthcoming "article" is an exquisite one of its kind, and will produce a most enlivening effect—if he will only let us have it fresh and sparkling, to begin the new year withal,

instead of suffering the spirit to ooze out by degrees through the pages of the *Lancet*.

NATIONAL VACCINE BOARD.

WE understand that this establishment is to be discontinued: if so, we trust that some efficient mode of keeping up the supply of vaccine lymph will be adopted.

WOUNDS FROM ROCKETS.

IT is rather a remarkable fact, that not fewer than four persons were brought to St. George's Hospital, the evening of the coronation, with wounds of the head from the shafts of rockets. In each instance, the wound was on or near the *left* temple, as if the head most naturally turned towards the right shoulder, in looking at an object nearly straight above the spectator. One of these lads lost his life, the others were severely wounded; and we allude to the circumstance at present for this reason, that we have been informed the rockets were procured from Woolwich, with loaded shafts, on purpose to make them go straight up, whereas care ought to be taken (as these instances show) to give them an oblique direction, so as, at least, to clear the ground occupied by the spectators.

INJECTION OF SALTS INTO THE VEINS IN CHOLERA.

WE perceive that a charge of a very absurd description was made against us at the Westminster Society on Saturday evening last by the gentleman who there and then read a paper suggesting a *new* method in the treatment of cholera. Certainly, considering the multitude of remedies proposed and tried in this fatal disease since its first introduction into Europe, to be able to hit on any thing new in that way, is a matter of some merit; but this is not what we have immediately to do with; we are not going to discuss the value, or probable value rather, of a remedy which has not as yet yielded any practical result; our present business is to settle the claim of the self-supposed originator of the method.

In our last number, under the head of "*remedies tried at Sunderland in cholera—others suggested,*" we took occasion to say,

after noticing some other things, "We earnestly recommend a trial of injecting medicated solutions into the veins, particularly some of the neutral salts, as muriate of soda;" and "we think that the views of Dr. Stevens, as to the effect of salts on the blood, to which we have repeatedly called attention, ought to be put to the test as speedily as possible." And this was the foundation of the charge of plagiarism—of course by anticipation—which the gentleman alluded to thought fit to bring against us. But, forsooth, the subject of the gentleman's paper was intimated (however obscurely) on that night week: *ergo*, it was "upon that hint we spake:" we "embezzled," in short, (for this was the polite expression used towards us) our suggestion from Dr. O'Shaughnessy's notice—whence else could we have had it? How superlatively ridiculous! We question if the desire of being thought a discoverer ever betrayed an individual into such a depth of absurdity. We would fain hope that Dr. O'Shaughnessy has thought better of it since, and that he is convinced, ere this, of the precipitate folly of his charge; but lest he should not be so, we shall take leave to set him right on the validity of his claims, and that with an overwhelming mass of evidence, the most incontrovertible.

Let us first, though, settle exactly what this new method or singular discovery is, that is laid claim to. The idea of injecting fluid into the veins in almost any unmanageable disorder now-a-days, is most assuredly no novelty: nobody would be so silly as to take merit to himself for simply proposing injection into the veins in cholera: the merit, then, in the present case, must be supposed to be centered in the proposal: 1, to oxygenate, or at least redden, the blood in cholera by the exhibition of salts; and, 2, to do it by injection. From the nature of the charge made on us, we conjecture that these are the meritorious points in the *new* method which are sought to be appropriated by Dr. O'Shaughnessy—but we shall at once shew how evanescently slender are the claims of this gentleman on both points to be considered as original.

It would be impertinent in us to presume our readers unacquainted with the views of Dr. Stevens relative to the condition of the

blood in malignant diseases—or his method of treatment founded on those views: we shall only beg to state expressly that they were given to the public through a paper read before the College of Physicians in May 1830, and of which an ample analysis was given in this journal at the time*. Since then we can refer our readers to the more ample and masterly communication from the same gentleman recorded in our pages about three months ago†, and the perusal of which drew from Dr. Prout the flattering opinion, that “it contained the germs of discoveries of the last importance to mankind‡.”

But even anterior to this last communication of Dr. Stevens, we had ourselves more than once had occasion to refer to his opinions—particularly in a leader on the Symptoms and Treatment of Cholera§; and again in a leading article, in which we detailed at some length our own impressions relative to the state of the blood, and the effect of saline medicines in malignant diseases||. We will not occupy our space with extracts from those papers, thinking it sufficient to give exact references to them; though we should be extremely glad, did our limits permit us, to insert at length the remarks of Dr. Sewall, of Washington, which will be found appended to the leader last referred to. This gentleman, after stating with admirable precision the results of Dr. Stevens's experiments, adds, “Whatever practical inferences or change in the treatment of diseases these experiments may lead us to, the idea that the red colour of the blood is owing to the saline matter which it contains is entirely new: and no one can deny to Dr. Stevens the merit of having been the first discoverer of this interesting fact¶.”

So much for the principle of the pretended new method. But, perhaps, the gentleman who stands candidate for all the honours it will bring him, rests his claim on the particular manner of applying the saline substance to the blood—by injection. Hear

what a valued correspondent of ours, Mr. Smart, of Cranborne, says, in an excellent paper on transfusion of blood in cholera:—“When I spoke of cholera as a ‘corrupter,’ I mean to allude to the changes which take place in the blood in that disease. This is a fact known to foreign pathologists; it is also known by Clanny and Stevens, that changes, perhaps similar changes, take place in the blood of typhous patients. Hence, there is some reason for assimilating the two diseases, as well as on the additional ground that, after the violence of the attack of cholera is past, fever of a typhoid character is apt to ensue. If the restoration of the healthy properties of the blood be so important a point in the treatment of typhus, as the researches of those gentlemen would affirm, and if this can be effected by the internal administration of carbonic acid gas or the neutral salts, I have long thought, *why should not those substances be directly conveyed into the current of the circulation by injection?*” These remarks are dated the 14th November, and were published in this journal in the very number which came out just before the meeting of the Westminster Society, at which Dr. O'Shaughnessy gave notice of his paper, that is to say, more than a week before the said paper was read.

Here we might stop, and conclude our observations with the question, who now is the *embezzler*?—but we have no wish to part on bad terms with Dr. O'Shaughnessy: we can allow much for the lengths into which the fond ambition of shining forth as a discoverer seldom fails to carry the youthful aspirant. We look upon his present exertication as highly creditable to his talent for chemical research; but most assuredly we cannot flatter him by professing to see *novelty* in it, except there be any in the proposal to use a particular salt (a variety of which will suggest themselves to every chemical investigator engaged in such experimental inquiries)—or if he lay any stress on the particular vein into which he would have the injection made (the external jugular), we can assure him that we think the *merit* of this suggestion completely overbalanced, by the singularly imminent hazard to which it would expose the life of the patient.

WESTMINSTER MEDICAL SOCIETY.

Saturday, Dec. 3, 1831.

Laws relative to Dissection.

On the motion of Dr. Somerville, seconded by Dr. Sigmond, the following resolution was unanimously carried:—

“That the Committee of the Westminster Medical Society be requested to prepare petitions to both houses of parliament to represent the difficulty which attends the study of anatomy from the scarcity of dead bodies, and pray for an alteration of the laws upon that subject.”

Nature and Treatment of Cholera.

DR. O SHAUGHNESSY opened the discussion by reading an elaborate paper on the propriety of injecting oxygenated salts into the veins in cholera, but we regret to say in so low a tone that a considerable part of it did not reach us. It commenced by stating that it was not without much hesitation that he (Dr. O'S.) had on previous occasions ventured to offer contributions to the society; the subjects, however, were of an experimental kind, and scarcely admitted of an argument being adduced against them. In the present instance his observations were strictly experimental, and therefore admitted of demonstration. From all the statements and history of cholera yet presented, it was evident, that notwithstanding the numerous therapeutical agents employed the disease sometimes began with such dreadful violence that medical aid failed in arresting its progress. For the truth of that assertion, sufficient evidence was to be found in the Warsaw epidemic, where the disease proved extremely fatal, notwithstanding that it was treated by a combination of the most devoted men that medicine had perhaps ever furnished to mankind. At Sunderland, the mortality of cases termed “malignant,” was so great that the experience of the past seemed almost valueless as to the future protection afforded against the malady by medicine. Hence it arose, that up to the present moment the most practical men in the profession were assiduously occupied in search of some more specific remedy than any which had been yet discovered. It devolved on practical chemists to inquire whether in the remote causes, in the physiology or pathology of this disease, any data could be discovered which might lead to the application of a remedy. It would be admitted that the chemical nature of the poison was unknown, some terming it animal, others vegetable, some aerial, and others terrestrial. Looking to the consecutive and remote causes, what were the common circumstances observed? What were the phy-

siological changes, if any? What were the chemical changes, if such there were? To answer those questions correctly, they must consider the disease both in its abstract and essential forms, divesting it of all accidental phenomena. What were the first effects of the remote causes? From the evidence of those who had witnessed the disease, it appeared that the effects were particularly observable in the sanguineous system. Hence the skin became blue, the secretions were suspended, the arteries contained black blood; no carbonic acid was evolved in the lungs, the returned air of respiration was as cold as when it entered those organs. Such were the primitive effects of the remote causes, and these gave rise to a third set of phenomena, to which it was unnecessary for him to revert on this occasion. The following questions, then, naturally suggested themselves. First, what was the alteration in the black and thickened condition of the blood, the state of arterialization, the impeded secretions, &c. by which the affection was attended? Secondly, what was the best mode by which that artificial state could be remedied? In considering the first question, they must admit that in all diseases it would of course be a proper procedure to counteract the remote causes, if they were visible, according to a rational mode. Having shewn the improbability of attaining a knowledge of those causes, were they justified in attacking its effects? Such a proceeding was not without a precedent in other cases, and it was generally acknowledged that this was the principle to be adopted in the treatment of the disease now under consideration. They found a great majority of practitioners earnestly recommending venesection, not as a sedative, not as an antiphlogistic, not as a blind empirical specific, but as the means of diminishing the venous congestion, of restoring the suspended circulation, of recovering the arterial quality of the blood, of which a bright scarlet hue was the outward and visible sign. Such was the recommendation of Dr. Johnson, Dr. Kennedy, and others who had reasoned on the phenomena of this complaint. Another class of physicians, embracing the same views, proposed by different means to attain the same desirable object; and in order to remedy the absence of arterialization, they recommended the inhalation of oxygenated gases, or the protoxyde of azote. Now it might rationally be expected that the success or failure of these methods would afford a touch-stone of some authority in deciding on the rationality of the principle on which they were practised. Accordingly, it was established by the most numerous writers that detraction of blood had removed the effect, and cured the disease. But before proceeding further, it was necessary to examine briefly into causes which interfered with the universality of ve-

venesection, and those might be found to reside in the debilitating influence, whether transient or partial, which the detraction of blood sometimes occasioned, and which, when added to the debilitating effects and remote causes of the affection, become sufficient to destroy the vital powers remaining in the system. Again, blood might not be procurable; and when they considered that the venous circulation was almost completely suspended in violent cholera, it could scarcely be a matter of surprise that the detraction of blood by venesection was frequently found to be unattainable. The inhalation of oxygen gas had failed, but that did not shew that the re-arterialization of the blood would not cure the disease. Many causes conspired to prevent the entrance of the gas into the circulation of the lungs. Again, the suspended action of the heart permitted but an insignificant portion of blood to be circulated, and the withdrawal of a certain portion allowed a new stratum to be acted upon by the inspired air. Let them next inquire, whether there did not exist some certain method of inducing arterialization, and that method free from the objections to which venesection and gaseous medication were exposed. It appeared to him (Dr. O'S.), that if they could bring a certain saline substance, highly oxygenated, freely into contact with the blood, they could restore the arterialized colour, and most probably alleviate the bad symptoms of the case. It was, however, obvious, that in a disease of such rapidity, one in which the circulation was almost suspended, and the intestines covered with a tenacious matter, it was in vain to suppose that time, as in the case of the yellow fever, would permit the absorption of materials taken into the alimentary canal. He, therefore, conceived the idea of injecting such substances into the veins as would restore the natural quality of the vital fluid. Before, however, so novel a practice could be put into execution, it was necessary to have a distinct notion of the effects of individual salts upon blood without the body, and when circulating in the living frame. Those which contained the greatest quantity of oxygen were the nitrate and chlorate of potassa. A few grains of those salts would change the colour of a larger quantity of blood than the pulmonic circulation generally contained. They also knew that the nitrate and chlorate of potassa entered the system from the intestines, and passed off in the urine—wherein they might be detected—without injuring the organization of the blood through which they passed. From those facts it was evident, that the injection of the substances he had just mentioned into veins could not possibly do mischief, but might effect much good. In corroboration of the probable efficacy of this mode of treatment, he briefly alluded to some experiments he

had made in prosecuting his toxological inquiries. In one series of experiments, from 10 to 60 grains of chlorate of potassa were injected into the cervical veins of a large dog, which seemed to experience little ill effects. The pulse rose in fulness and frequency; he passed urine copiously in a quarter of an hour, which evidently contained the chlorate. Blood was drawn from the brachial vein, and presented a fine red colour. In another series of experiments, the dog was brought into a state of asphyxia, and when he was apparently dead, half a drachm of chlorate of potassa was injected into the jugular vein. The pulsation of the heart returned, and in twenty minutes he passed urine, containing the injected salt. He (Dr. O'S.) trusted he should not be mistaken as supposing that the practice of injecting into the veins would prove equally successful in cholera; but these experiments seemed to him to prove, that by injecting the nitrate or chlorate of potassa, the blood was restored to its arterial tint, and the process of circulation and arterialization thereby accelerated. In cases of cholera, he would recommend injecting into the jugular vein where it crossed the sterno-mastoideus muscle. The syringe used for the injection should not contain more than two or three ounces; the solution should be injected warm; the tube should not be more than an inch long, and gently curved, in order to assist manipulation. In performing the operation, he would merely make a puncture in the vein, and not detach it from the surrounding parts. The injection should be made deliberately; from 10 to 30 grains of the salt might be employed. It would be desirable, before the experiment was tried minutely, to analyze cholera blood; for, to his mind, no satisfactory analysis had yet been completed. He then briefly recapitulated the advantages which he thought likely to result from the plan he had proposed, and proceeded to remark, that he was unwilling to trespass farther on the time of the society, or he might derive an additional argument from the recent experiments on the blood by Drs. Prout, Christison, and others. He had intended to draw collateral support from Dr. Stevens's experiments, but he understood the doctor was shortly about to publish his work on that subject, and therefore he (Dr. O'S.) had foregone his original design. Before he concluded, he had to call the attention of the society to a recommendation, similar to his own, proposed in the Medical Gazette of that day, and which was nearly similar to the notice he had given at the preceding meeting. If the present were a time for private feeling, he might appeal to the gentleman who presided on the last occasion—to the secretary—to the meeting itself, whether he did not distinctly make

the proposition;—he might appeal to Dr. JONXSON, or he might appeal to the reporter of the Gazette himself; but he would forego all feeling of rivalry, whether the person who availed himself of his (Dr. O'S.) remarks were the Editor of the Medical Gazette or any other—for he thought it unlikely that any member of the profession could be wilfully guilty of *the baseness of thus embezzling* the ideas and suggestions of another—and would merely remark, that he was pleased his opinions had received support from so respectable a quarter. There was, however, this difference between them;—the Medical Gazette recommended the injection of common salt, and he (Dr. O'S.) advised the nitrate or chlorate of potassa. He would venture to remind the editor of the journal in question, that the chloride of sodium, though it reddened venous blood, did not oxygenate it, because it contained no oxygen. There were many substances capable of reddening the blood that would not oxygenate it. He thought so far as theory went, that the salts he had proposed were likely to afford greater therapeutical advantages than those proposed in the Medical Gazette.

Dr. MACLEOD rose and said, that being well acquainted with the contents of the Medical Gazette, he could positively state that the charge of pirating Dr. O'Shaughnessy's opinions was wholly and entirely groundless, inasmuch as every circumstance mentioned, and every suggestion thrown out, had been made in the pages of the Gazette before Dr. O'Shaughnessy's paper had been read, or its announcement taken place. The effect of the neutral salts on the blood had over and over again been pointed out by various writers in the Gazette, as all who read it must be fully aware; and however ingenious Dr. O'Shaughnessy's paper might be, not the least proof of that ingenuity was the manner in which he had contrived to bring forward his ideas with so little allusion to Dr. Stevens, to whom, and to whom alone, was due all the merit that belonged to novelty. He (Dr. M.) stated that Dr. O'Shaughnessy was in error in asserting, that common salt injected into the veins contained *no* oxygen. No one dreamt of injecting dry chloride of sodium; and any one acquainted with chemistry knew, that when thrown into water, the sodium became united with oxygen to form soda. He did not mean that the oxygen was likely to be separated by the blood, because he suspected that the change of colour was dependent on quite a different cause: he merely wished to answer Dr. O'Shaughnessy's remark on that particular point. The very identical proposal of injecting nitrate of potass into the veins, now adduced by Dr. O'Shaughnessy, had been made a fortnight ago by a writer in the Medical Gazette, and he had

himself been engaged in some experiments upon the subject. [Dr. Macleod then detailed these, but as he has described them in a letter, inserted at page 357, we omit this part of his speech.]

Dr. JOHNSON here made some remarks, which we deem it unnecessary to insert, as they are embodied in his letter, at page 357.

Dr. MACLEOD said, he was extremely mortified to hear such a charge against Dr. Stevens; but that he had nothing to do with his accuracy or inaccuracy; he merely maintained, that whatever merit there was, be it great or small, in the proposal of using the neutral salts to change the state of the blood, was exclusively his.

Dr. BLICK then rose and said, that it appeared to him that if they were to come to any thing like a legitimate conclusion on the propositions of Dr. Johnson, they ought to be taken *seriatim*. [This Dr. Blick accordingly proceeded to do, amid some confusion, and speaking in a low tone, was imperfectly heard. He argued in favour of the identity of the Indian and English cholera.]

Dr. SIGMOND now claimed the attention of the Society, while he adverted to the identity of the disease. It was supposed that the cholera, mentioned by Sydenham, more or less resembled the Asiatic disease; but he agreed with Dr. Copland that the diseases differed in every point of view. Sydenham was in the habit of sitting down by the bedside of the patient, and correctly noting every symptom. Small-pox and gout had been described by him in the most accurate manner, and of cholera he had given six particular symptoms. Sydenham, however, in his six symptoms, spoke of cholera, dysentery, and griping, as being very common in a certain year. Dr. Sigmond then produced several ancient bills of mortality, published during the years in which Sydenham wrote his account, in which an immense number of persons were described as having died of "griping of the guts," and proceeded to remark that Sydenham made use of the word cholera when speaking of bile. The list of the six symptoms of which Sydenham spoke, was that of collapse, which he described as frightening the by-standers, and carrying the patient off in 24 hours. He (Sydenham), however, preceded that statement by remarking, that the disease seldom or never occurred except during the months of September and October, and that it was not to be mistaken for a surfeit. He did not speak of the cold breath, nor of the blue appearance of the body, two circumstances which it was impossible to believe could have escaped the notice of so accurate an observer, had they occurred in any patient under his care. The disease described by Sydenham was totally different from the Asiatic cholera. There was not one of the old writers who described the blue symp-

toms and the cold breath. They described the gripings, twistings, and convulsions, arising from a flux of the bowels, but not that extraordinary intestinal state which occurred in this disease. With respect to the observations of Dr. Johnson, as to the affections arising from some peculiar changes in the earth, it was a remarkable coincidence that plague, when first described, was considered to proceed from the same circumstance. Earthquakes, comets, &c. took place prior to the occurrence of both these malignant affections; but he (Dr. S.) could not trace any connexion between the supposed cause and effect; and it appeared to him that the cholera arose from a poison immediately affecting the brain. The Indian medical men, though of high talent and great research, found a disease with which they were unacquainted before: they did not know what name to give it, and therefore gave it one with which they were best acquainted, as producing most dreadful symptoms, namely, cholera. They were the first persons to name it, and did so from mere comparison.

Mr. BOYLE would not have trespassed upon the patience of the meeting, but for the conflicting opinions which prevailed as to the actual symptoms of the disorder under discussion. He had seen cholera as it existed in various parts of the world, and the distinctions between Indian and common cholera, he believed, were not to be found in the state of collapse, in the dark areolæ around the eyes, or the severity of the spasms; but in epidemic cholera there were spasms producing a wrinkled state of the fingers, there was coldness of the tongue, cold breath, and the absence of bile. The wrinkling of the fingers deserved particular attention, for he had never seen a case terminate fatally, unless that symptom were present. With regard to Dr. O'Shaughnessy's paper, he, as a practical man, must say that he did not think it was applicable to this subject. Dr. O'Shaughnessy seemed to think that if he could change the appearance of the blood, he would cure his patient; but it must be recollected that there were other symptoms present besides the want of oxygenation of the blood, and remedying that defect would afford no relief to the other symptoms. Mr. Boyle then referred to the opinions he expressed on the last evening of discussion, as to the pathology of the affection consisting essentially in obstruction of the gall-ducts, from which he again deduced an argument in favour of emetics, which, he said, was materially strengthened by the plan adopted by Dr. Barry, of administering salt and water, which must act on the same principle as emetics.

Mr. KING rose in consequence of the opinion expressed by Mr. Boyle, as to the obstruction of the biliary ducts. He had opened nearly a *thousand* bodies! and in

about one-half he had been unable to make the bile pass from the gall-bladder into the duodenum. After some farther rather desultory observations, the speaker went on to give an account of a case of cholera, which he had attended in conjunction with Mr. Lobb, of Aldersgate-street. "The old woman" was so severely attacked by the disease that he (Mr. King) thought recovery impossible; but to his great astonishment, in consequence of the application of a mustard poultice by himself (adopting Dr. Blick's suggestion, or rather anticipating it), about eighteen inches square—[Some one in the gallery at this moment exclaimed, Hear, hear, hear! in the loud and solemn manner in which Mr. King is wont to do so—the imitation was perfect, and produced long and loud bursts of laughter, by which the speaker was for some time interrupted]—I say, eighteen inches square over the whole abdomen: the patient speedily rallied. The laughter which accompanied the recital of this case induced the speaker, at the conclusion of his narrative, to vociferate, that if the audience did not believe him, they might make inquiries at No. 92, in Fleet-street, where the patient herself would corroborate all his statements. He then concluded by deprecating the practice of injecting the jugular vein, as proposed by Dr. O'Shaughnessy, on account of the danger of exciting phlebitis.

Dr. WEBSTER hoped that at the next meeting he should have in his power to lay before the Society a communication from Nottingham, relative to the prevalence of cholera in that town about ten or twelve years ago, at which period the mortality was from twelve to fifteen persons daily. He had also heard that the disease once prevailed to a fearful extent at Rochester. He concluded by repeating some of his former observations relative to the identity of cholera.

Mr. ——— begged to correct two slight errors; the one committed by Dr. Macleod, and the other by Dr. Sigmond. Dr. Macleod had spoken of Dr. Stevens as having been the first person who introduced a knowledge of the deranged state of the fluids, in opposition to the French doctrines of solidism. That honour was due to Dr. Clanny, of Sunderland. Dr. Sigmond had spoken of Servetus, as having first discovered the circulation of blood; that great physiologist merely discovered the pulmonary circulation.

Dr. O'SHAUGHNESSY replied very briefly, that he had little to say which would not involve a repetition of the arguments read in his paper. He objected to Dr. Macleod's experiments, as by that gentleman's own showing he had *burked* the rabbits, and it was not to be expected that an animal actually dead could be resuscitated.

The Society was then adjourned. The debate is to be introduced this evening by Mr. Searle.

MEDICO-BOTANICAL SOCIETY.

Twelfth Session.

This society commenced its sittings last month, and reports of two meetings have been lying on our table, but cholera has so fearfully overspread our pages, and travels still with such alarming rapidity up one column and down another, that we can even now afford but little space for noticing two curiously interesting papers which were read to the Fellows at the two November meetings.

The first, communicated by Dr. Walsh, (accompanied with specimens, not only of the plant itself, but also of the alluvial soil on which it grows, the subjacent rock, &c. &c.), related to the "*Fungus Militensis*" of the isle of Gogo, which was once so highly valued by the Knights of Malta that a constant guard was kept for its especial preservation.

The second essay, by M. Bonastre, of Paris, and translated by the Secretary, contained a particularly interesting detail of certain vegetables found growing in the tombs of Egypt, of a totally different kind to those which form the present circumjacent flora. We only regret our inability to do more than announce the subject of this paper, which excited, and most deservedly, very general attention.

The Professor of Botany likewise offered some important observations on the laws of "Isomorphism," or "Homomorphism," in vegetables, of which we shall probably give a further account on some future occasion. The Society, at its rise, adjourned to Dec. 13th, when it was announced that a lecture would be delivered by the Professor, "On the Connexion of Medical with General Botany."

MEDICAL SOCIETY OF LONDON.

On Monday, November 28th, a paper on cholera, comprising an account of an epidemic English cholera, which appeared amongst his Majesty's ships in ordinary, in the river Medway, in the months of July, August, and September of the present year, was read to the Society, written by Mr. James Hall, the surgeon of the ships in ordinary at Sheerness, a corresponding member of the society. The subject of cholera was resumed on Monday last, and will be again discussed on Monday next.

REPORTS OF CASES OCCURRING AT PUBLIC INSTITUTIONS.

ST. BARTHOLOMEW'S HOSPITAL.

Ligature of the Common Carotid—Excision of Superior Maxilla.

WE subjoin an account of a very interesting operation performed by Mr. Earle last Saturday. Our report may appear rather tame after the highly-coloured one which appeared

in the newspapers, but we have reason to believe that it is very accurately drawn up. The operation, though not common, we need scarcely say is not new; and we ourselves had occasion to record its performance at the London Hospital, by Mr. John Scott, less than a year ago*. Mr. Scott tied the external carotid; Mr. Earle preferred taking up the common trunk. The forceps used in both was Liston's, made very strong, and slightly modified; indeed, we believe the identical instrument was used in both. It is but justice towards Mr. Earle to remark, that the operation was performed with the greatest dexterity and coolness; but we strongly disapprove of the manifestation of feeling to which it subsequently gave rise in the operating room. They who make a successful operation the subject of testifying approbation, will also hold themselves entitled to visit an unsuccessful, though perhaps not less skilful performance, with marks of their displeasure; and it would be difficult to imagine any thing more calculated to injure the cause of operative surgery than such displays. We are informed that Mr. Earle, with the candour which those who know him would expect, spoke in the handsomest manner of the assistance afforded him by Mr. Scott. Our reporter states that, at the commencement of his clinical lecture on Wednesday last, Mr. Earle, after reporting the progress of the case, took the opportunity of publicly expressing his thanks to Mr. Scott, for the readiness with which he had come forward, and for the many valuable hints and able assistance which he had rendered him. "It is thus," he concluded, "that men attached to public institutions ought always to act. We should render every assistance to one another, and be rivals only in doing good."

Mary Cave, æt. 45, was admitted into the hospital under the care of Mr. Earle, November 20th. She had always enjoyed good health until about two years ago, when, after a blow, which she received on the right cheek, she perceived a slight swelling beneath the infra-orbital ridge, attended with pain, which she compared to a face ache from cold. This swelling continued to increase, though in no very marked degree, until last August, when the tumor began to extend itself through the front of the superior maxillary bone and alveolar processes into the mouth, she having lost the teeth of that side some considerable time previously. This induced the patient to apply to a surgeon at St. Albans, who lanced it, and afforded her some relief; but from that time the disease increased rapidly, causing a greater projection of the cheek, and nearly filling the mouth. Nothing was done to it from the month of August up to the present time. By reference to the sketch, it will be seen that

* See Medical Gazette, vol. vii. p. 236.

the diseased mass projects some distance from the mouth, which it nearly fills: that portion which is seen in the left side of the mouth is moveable, and having no connexion with the left maxillary bone. The tongue was pressed upon and much confined by the tumor, causing considerable difficulty of deglutition. The offensive fœtor was very distressing. No enlargement of the cervical glands, or any apparent disease in other parts of the body.

The operation was performed on Saturday, the 3d inst. in the following manner.

As a preliminary step, Mr. Earle secured the common carotid artery, which was done with great facility. A strong flat silk ligature was passed round the vessel, and tied with a slip knot, so gently as not to divide the inner coats of the artery; a small portion of cork being interposed, to act as a tourniquet and facilitate the removal of the ligature at the conclusion of the operation, should it be found that any ill consequences to the brain resulted from its application.

The patient being supported with pillows, the first incision was made, extending from about a quarter of an inch from the inner angle of the eye, downwards by the side of ala nasi, to about the same distance from the commissure of the lips. A second incision extended from the mouth through the cheek, beyond the anterior edge of the masseter muscle, below the course of the parotid ducts. This triangular flap was then dissected from the front of the tumor upwards, as high as the orbit. The parts contained in the latter were next separated, by means of a curved

silver scalpel, from the floor of the cavity; the interior oblique muscle of the eye being detached at its origin, and the infra orbital nerve divided before it entered the canal. The front of the tumor and adjacent bones being thus exposed, Mr. Earle, with a large pair of Liston's forceps, divided the malar bone close to its junction with the superior maxillary bone. The forceps entered the sphenomaxillary fissure, and cracked the orbital plate of the superior maxillary bone transversely across, an inch posterior to the infra orbital ridge. The forceps were then applied to the nasal process of the superior maxillary bone, which was divided at about the middle of the groove of the nasal duct. The first incisor tooth on the right side was next drawn, and the superior maxillary bone cut through close to the symphysis. The tumor, and bones to which it was connected, were now almost isolated, and only retained their posterior attachments. During the removal of that part of the tumor connected with the bones, it was separated from the other part contained in and projecting from the mouth; this latter portion required to be dissected from the back part of the cheek and tonsil. The removal of this diseased mass being completed, a large clasm was formed, at the bottom of which were seen the fauces and cavity of the nose.

No hæmorrhage took place during the operation. The ligature was then loosened, and the cork removed, when some slight bleeding was apparent from the internal maxillary artery. As the patient was rather faint, it was apprehended that the hæ-

morrhage might increase; and as no bad effects had resulted from the temporary compression, a common silk ligature was connected with the flat one, which was withdrawn, and the artery finally secured in the usual manner.

The edges of the wound were then accurately brought together with hare-lip pins and sutures; and the patient was put to bed, and forty minims of laudanum administered in a little wine.

Towards the evening the pulse rose considerably, and fourteen ounces of blood were taken from the arm. The patient has not had one bad symptom since. The whole extent of the wound is nearly united by the first intention, with the exception of part of the upper lip. The pins have been removed, and some of the sutures.

On examination of the tumor, all the parietes of the antrum, excepting the orbital plate, were found to be absorbed. A thin plate of newly-formed bone inclosed the upper part of the tumor, which was of a firm sarcomatous structure, with spiculae of bone intermixed. Similar plates of bone were irregularly dispersed through the tumor. The lower portion, projecting into the mouth, was of a softer texture, and approached in character to the medullary sarcoma.

December 9th.—The patient is going on as well as possible.

OUR EXTRA SHEETS.

WE think it right towards our readers to inform them, that it is not intended to increase the size or raise the price of this journal; and at the same time to explain the circumstances which have led us, on several recent occasions, to give an additional sheet. The number of papers sent to the Gazette during some weeks past, has been so great, that it would not have been possible to have inserted them all, even if the whole journal had been devoted to that purpose alone. We have, therefore, thought it better to give occasionally an extra sheet, rather than either disappoint—perhaps offend—many valuable contributors, or sacrifice the other departments of our paper. Many of the communications relate to Cholera—a subject which, after a time, must become exhausted, so that we do not contemplate being frequently obliged to trespass upon our subscribers. We have still to apologize to several gentlemen for the postponement of their papers, for which we have been unable to make room this week, notwithstanding the omission of Dr. Thomson's Clinical observations; it will be seen, however, that besides the Lectures on Medicine and on Surgery, we have inserted, in the present number, not fewer than thirteen Original Communications, all bearing the names of the contributors—a circumstance by which we have been partly guided in the selection made.

HOT AIR BATHS.

It is but justice towards Mr. Green to state, that his baths are not made by him for sale, as the notice in our last number might seem to imply. Mr. Green has, at much expense, constructed very efficient baths at his own house, where they are open to the inspection of the profession.

METEOROLOGICAL JOURNAL

Kept at EDMONTON, Latitude 51° 37' 32" N.
Longitude 0° 3' 51" W. of Greenwich.

Rain fallen, .325 of an inch.

NOTICES.

The communications of Mr. Huntley, Dr. Tweedale, Dr. Negri, Mr. Bennett, Dr. Badeley, a General Practitioner, Mr. Crowdy, Mr. Alsop, Dr. Burke, Dr. Holbrook, J. F., and F. A. B., have been received.

Dr. Blackmore and Dr. Tweedale in our next.

Dr. Gilchrist.—We are sorry that our reporter should have mistaken the doctor; but having inserted, in our last number, his denial of being influenced by personal feeling, we must decline doing anything farther in the matter.

Medicus, M. D., and X. Y., are respectfully informed, that GALVANISM having already been repeatedly suggested, we do not think it necessary to insert their letters.

"A Chemist and Druggist," who writes in answer to Mr. Greening, is too personal. We have no objection to insert the fullest vindication of his "order;" but, as he does not give his name, he must speak of events, not individuals.

"X."—We shall inquire about it, and perhaps be able to give the information desired next week.

"Physicus" is under consideration.

ERRATUM.

Some accident occurred in the arrangement of the types in passing from the second to the third sheet of our last number; we shall set it to rights on resuming our analysis of Dr. Bright's work, in which the mistake took place.

On the 1st of January, 1832, will be published, Part I. price 5s.

OF THE

CYCLOPÆDIA

OF

PRACTICAL MEDICINE;

COMPRISING

TREATISES ON THE NATURE AND TREATMENT OF DISEASES,
MATERIA MEDICA AND THERAPEUTICS,
MEDICAL JURISPRUDENCE, &c.

EDITED BY

J. FORBES, M.D. F.R.S.	ALEX. TWEEDIE, M.D.	J. CONOLLY, M.D.
Physician to the Chichester Infirmary, &c.	Physician to the London Fever Hospital, &c.	late Professor of Medicine in the London University, &c.

LONDON:

SHERWOOD, GILBERT, & PIPER, AND BALDWIN & CRADOCK,
PATERNOSTER-ROW;

WHITTAKER, TREACHER, & CO. AVE-MARIA-LANE.

The want of a comprehensive work on subjects connected with PRACTICAL MEDICINE, including PATHOLOGY and PATHOLOGICAL ANATOMY, is one which has long existed in this country. The Medical Dictionaries heretofore published, and the Systems of Medicine in the hands of the student, may be said, without invidiousness, to fall very far short of presenting the English reader with such a compendious survey of the actual state of BRITISH and FOREIGN MEDICINE as is absolutely required by him. Some of them are too limited and too superficial in their character; others are too voluminous, too intricate in their arrangement, and too indiscriminate in their contents; and all are open to the serious objection of failing to represent the improvements and discoveries by which the scientific labours of the members of the medical profession, in various parts of the world, have been rewarded since the commencement of the present century.

It is the object of the CYCLOPÆDIA OF PRACTICAL MEDICINE to supply these deficiencies, and to meet the acknowledged wants of the medical reader. Such ample arrangements have been made for effecting these important objects, as enable the Editors to lay before the public the nature and plan of a publication in which they have endeavoured, by dividing the labour of a work including subjects of great diversity, and all of practical importance; by combining the valuable exertions of several contributors already known to the medical public; by excluding mere technical and verbal explanations, and all superfluous matter; and by avoiding multiplied and injudicious divisions; to furnish a book which will be comprehensive without diffuseness, and contain an account of whatever appertains to practical medicine, unembarrassed by disquisitions on subjects extraneous to it.

In pursuance of this design, every thing connected with what is commonly called the PRACTICE OF PHYSIC will be fully and clearly explained. The subject of PATHOLOGY will occupy particular attention, and ample information will be given with relation to PATHOLOGICAL ANATOMY.

Although the excellent works already published on the subjects of MATERIA MEDICA and MEDICAL JURISPRUDENCE can be so readily and advantageously consulted, as to make the details of those branches of science uncalled for in the Cyclopædia, it belongs to the proposed plan to comprise such notices of the application and use of medicinal substances as may be conveyed in a general account of each class into which they have been divided, as of TONICS, NARCOTICS, &c.; and to impart, under a few heads, as TOXICOLOGY, SUSPENDED ANIMATION, &c. such information connected with Medical Jurisprudence as is more strictly practical in its character.

It is almost unnecessary to say that a work of this description will form a LIBRARY OF PRACTICAL MEDICINE, and constitute a most desirable book of reference for the GENERAL PRACTITIONER, whose numerous avocations, and whose want of access to books, afford him little time and opportunity for the perusal of many original works, and who is often unable to obtain the precise information which he requires at the exact time when he is in greatest need of it.

The STUDENT OF MEDICINE, who is attending lectures, will also, by means of this work, be enabled, whatever order the lecturer may follow, to refer, without difficulty, to each subject treated of in the lectures of his teacher; and it is presumed that Lecturers on Medicine will see the advantage

of recommending to their pupils a work of highly respectable character, the composition of original writers, and which, it is hoped, will neither disappoint the advanced student by its brevity and incompleteness, nor perplex those commencing their studies by an artificial arrangement.

But, whilst the Editors have felt it to be their duty to prepare a safe and useful book of reference and text-book, it would be doing injustice to those by whose co-operation they have been honoured, not to avow that they have also been ambitious to render the work acceptable and interesting to readers who have leisure and inclination to study what may be termed the *PHILOSOPHY OF MEDICINE*: whatever is truly philosophical in medicine being also useful, although the application of the science to the art requires much reflection and sound judgment.—For the assistance of those who desire to pursue a regular course of medical reading, ample directions will be given when the work is completed; and for those who may be anxious to prosecute any particular subject to a greater extent than the limits of the *Cyclopædia* permit, a list will be given, in an Appendix, of the best works relating to each.

The means of accomplishing an undertaking of the importance of which the Editors are fully sensible, will, doubtless, be appreciated after an inspection of the list of contributors who have already promised their co-operation. It is, of course, desirable that a work of this kind should be characterised by unity of design, but, at the same time, as each author will, generally speaking, contribute his knowledge and his opinions on the subjects which have occupied his chief attention, the superiority of the whole performance to any thing which the mere labour of compilation could accomplish will be unquestionable. To each important article the name of the author will be appended.

The acknowledged want of such a publication, already alluded to, and the extensive encouragement which Dictionaries of much greater extent have met with in *FRANCE* and *GERMANY*, although some of them are very unequal as regards the value of different parts, and encumbered with much that is absolutely useless, afford sufficient reason to hope for the success of a work in which what is valuable will, as much as possible, be separated from what is merely calculated to distract the attention, and to frustrate the inquiry, of those who study the science of medicine with a view of regulating and improving its practice.

In order to insure this success, it is the desire, and will be the endeavour of the Editors to make the *CYCLOPÆDIA OF PRACTICAL MEDICINE* not only obviously useful to those for whom it is more immediately intended, but so creditable to *BRITISH MEDICAL SCIENCE* as to deserve and to obtain the patronage of all classes of the Medical Profession.

CONDITIONS.

I. The Work will be published in Parts, and printed on superfine Paper, in a small Type, with double Columns, and in the largest Royal Octavo Size.

II. The first Part will be published on the 1st of January, 1832; and the Work will be continued on the first Day of every Month, until the whole is completed. Each Part (price 5s.) will contain as much Matter as is found in an equal Number of Pages of the large Quarto Encyclopædias.

III. The Arrangements made by the Publishers are of such a Kind as to enable them to engage for the regular Appearance of the Work, in London, Edinburgh, and Dublin, on the First Day of every Month.

CONTRIBUTORS

TO THE

CYCLOPÆDIA OF PRACTICAL MEDICINE.

- JAMES APJOHN, M.D. M.R.I.A. Professor of Chemistry to the Royal College of Surgeons in Ireland.
- EDWARD ASH, M.D. Physician to the Norwich Dispensary.
- JAMES L. BARDSLEY, M.D. Physician to the Manchester Royal Infirmary, Dispensary, &c.
- EDWARD BARLOW, M.D. Physician to the Bath United Hospital and Infirmary.
- JOSEPH BROWN, M.D. Physician to the Sunderland and Bishopwearmouth Infirmary.
- THOMAS H. BURDER, M.D. Member of the Royal College of Physicians, London.
- JOHN BURNE, M.D. Physician to the Carey-street Dispensary.
- ROBERT CARSWELL, M.D. Professor of Morbid Anatomy in the University of London.
- II. W. CARTER, M.D. F.R.S.E. Fellow of the Royal College of Physicians, London, Physician to the Kent and Canterbury Hospital.
- JOHN CHEYNE, M.D. F.R.S.E. M.R.I.A. Physician General to the Forces in Ireland, &c.
- JAMES CLARK, M.D. Physician to St. George's Infirmary, &c. &c.
- JOHN CLENDINNING, M.D. Fellow of the Royal College of Physicians, London.
- HENRY CLUTTERBUCK, M.D. Physician to the General Dispensary.
- JOHN CRAMPTON, M.D. M.R.I.A. King's Professor of Materia Medica, Physician to Steevens's Hospital, &c. Dublin.
- ADAIR CRAWFORD, M.D. London.
- ANDREW CRAWFORD, M.D. Physician to the Hampshire County Hospital, Winchester.
- WILLIAM CUMIN, M.D. Member of the Faculty of Physicians, Glasgow.
- JOHN DARWALL, M.D. Physician to the Birmingham General Hospital.
- JOHN ELLIOTSON, M.D. F.R.S. Physician to St. Thomas's Hospital, and Professor of Medicine in the London University.
- J. GILKREST, M.D. London.
- GEORGE GOLDIE, M.D. Physician to the York County Hospital.
- GEORGE GREGORY, M.D. Physician to the Small Pox Hospital.
- MARSHALL HALL, M.D. F.R.S.E. Member of the Royal College of Physicians, London, &c.
- THOMAS HANCOCK, M.D. Liverpool, Member of the Royal College of Physicians, London.
- BISSET HAWKINS, M.D. Fellow of the Royal College of Physicians, Professor of Materia Medica and Therapeutics in King's College, London.
- J. HOPE, M.D. Member of the Royal College of Physicians, London.
- ARTHUR JACOB, M.D. M.R.I.A. Professor of Anatomy to the Royal College of Surgeons in Ireland.
- WILLIAM KERR, M.D. Physician to the Northampton General Infirmary.
- ROBERT LAW, M.D. Fellow of the King's and Queen's College in Ireland, Physician Extraordinary to Sir Patrick Dun's Hospital.
- ROBERT LEE, M.D. F.R.S. Physician to the British Lying-in Hospital.
- CHARLES LOCOCK, M.D. Physician to the Westminster General Lying-in Hospital, &c.
- H. MARSH, M.D. M.R.I.A. Professor of the Principles and Practice of Medicine to the Royal College of Surgeons in Ireland, &c. Dublin.
- J. A. PARIS, M.D. F.R.S. Fellow of the Royal College of Physicians, London.
- J. C. PRICHARD, M.D. F.R.S. Physician to the Infirmary and to St. Peter's Hospital, Bristol.
- JONES QUAIN, M.B. Professor of Anatomy and Physiology in the London University.
- ARCHIBALD ROBERTSON, M.D. Physician to the Northampton General Infirmary.
- P. M. ROGET, M.D. Sec. R.S. Consulting Physician to the Queen Charlotte's Lying-in Hospital and to the Northern Dispensary, &c.
- JOHN SCOTT, M.D. Edinburgh.
- WILLIAM STOKES, M.D. Physician to the Meath Hospital, Dublin.
- A. T. THOMSON, M.D. F.L.S. Professor of Materia Medica in the London University.
- THOMAS THOMSON, M.D. F.R.S.L. and E. Regius Professor of Chemistry in the University of Glasgow, &c.
- T. J. TODD, M.D. Physician to the Dispensary, Brighton.
- RICHARD TOWNSEND, A.B. M.D. M.R.I.A. Fellow of the King and Queen's College of Physicians, Dublin.
- JOHN WHITING, M.D. Member of the Royal College of Physicians, London, Physician to the Surrey Dispensary, &c.
- CHARLES J. B. WILLIAMS, M.D. Member of the Royal College of Physicians, London.

THE Work may be obtained from every Bookseller in the United Kingdom; therefore Subscribers who are desirous of having it delivered to them on its publication are requested to give immediate orders to their respective Booksellers.

The arrangements made by the Proprietors are such that the Work will be sold throughout the UNITED STATES OF AMERICA at the same price as in Britain, and that each Part shall be published in America on the day of publication in London.

WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

SATURDAY, DECEMBER 17, 1831.

LECTURES

ON

THE THEORY AND PRACTICE OF
MEDICINE ;

Delivered at the London University,

By DR. ELLIOTSON.

PART I.—LECTURE XI.

*Varieties of Inflammation, according to its Seat
and other circumstances.*

I HAVE mentioned, gentlemen, the general symptoms, the general course, and the general consequences of inflammation, and I have now to speak of the varieties which take place in all these three particulars from certain circumstances.

Varieties according to the Structure affected.

In the first place I shall direct your attention to those varieties which are occasioned by the particular structure of the part in which the inflammation chancas to occur. The consideration of the varieties induced in inflammation by the structure affected, was first thought of, I believe, by Dr. Carmichael Smith, who published in the second volume of the Medical Communications, printed in 1788, a very admirable and classical paper on this subject. He it is, I think, who really has the merit of first considering diseases according to the structure which they affect; he, however, considered only inflammation. Nearly ten years after this, Pinel, a celebrated French physician, adopted this same arrangement, and he, I believe, upon the continent generally has the credit, while our countryman is overlooked. Bichat, in his General Anatomy, afterwards pointed out that all diseases, indeed, might be considered according to the structure which they affect.

There are five chief structures which Dr. Carmichael Smith considered as giving rise to the most decided varieties in the symptoms of inflammation, and these are the skin,

the mucous membranes, the serous membranes, the cellular membrane and substance of the organs; and, according to him, the muscles, but we ought rather, perhaps, to say the fibrous membranes, such as ligaments and aponeuroses, tendons, and the periosteum.

Skin.

When the part inflamed is the skin, it exhibits an intense shining redness, which is instantly removed by pressure of the finger, and as instantly returns, or nearly so, when the finger is removed; so that you make the skin white, but almost as soon as you remove the finger, you find a blush pervading the part, and then it becomes as red as before. If this inflammation of the skin be of a simple character, and in a patch, if there be nothing more than the inflammation of the part, the term given to it is *erythema*. It is not every inflammation which is erythema, but the simplest patch of inflammation on the skin is so designated.

The character of the pain when the skin is inflamed is burning and smarting, and when the inflammation subsides, it is frequently followed by the separation of the cuticle in branny particles, or scales, or even large shreds. This process is called *desquamation*.

Very frequently when the skin is inflamed we have vesicles appear, of various sizes; and not unfrequently there is a very great effusion of serum into the subjacent cellular membrane; so that where the skin is inflamed, the whole part becomes swollen, puffy, œdematous. As the skin is a continuous surface, every inflammation of it which is entirely superficial has a great tendency to spread, and sometimes when that takes place the part first affected recovers itself, so that the disease appears to wander along the body like a cloud, forsaking one part and going to another. But on the other hand, you sometimes have the part originally inflamed still affected, the disease having merely extend itself still farther. Sometimes the inflammation does not spread in this

way, but dips down, so that the cellular membrane below not merely becomes filled with serum, but becomes the subject of actual inflammation. If this occur in mere points matter may be formed, and you have what are called *pustules*, a number of little minute collections of pus. Sometimes they may be formed, indeed, without the cellular membrane being affected, the surface of the skin alone being attacked; but frequently the pustules exist also through the skin, deep in the cellular membrane. Sometimes, however, frightful extensive inflammation of the cellular membrane takes place, suppuration being very likely to occur, and then the disease is designated *erysipelas phlegmonoides*, or as some choose to call it, *diffused inflammation of the cellular membrane*. You therefore see that the skin may be inflamed superficially, and remain so, or the inflammation may dip down into the cellular membrane below, and then you have all the characters of inflammation of the cellular membrane in addition to those of inflammation of the skin. This may be considered a complicated disease, at least an inflammation of two parts.

Mucous Membranes.

The second structure which gives variety to inflammation is the mucous membranes. Mucous membranes, you know, are very nearly allied in structure, and in all other qualities, to the skin. You will find in Bichat's beautiful Treatise on Membranes the analogy between mucous membranes and the skin pointed out. It is a work well worth your study. When a mucous membrane is inflamed, it becomes thicker than usual, its temperature increases, and it is tender to the touch. The pain which is experienced is dull and diffuse, and sometimes it is of a pricking character, but if not pricking, it is obtuse and diffused. When the inflammation first begins, the secretion of the part is increased; it is, however, watery, or thin, and perhaps acrid. This any one may observe in a common catarrh. When a cold begins in the Schneiderian membrane of a nostril, the nose runs, the secretion is increased, but the secretion at first is not very excessive, nor is it thick but thin; frequently, however, it is more or less acrid. As the disease advances, the discharge becomes, perhaps, entirely suppressed, no secretion, perhaps, takes place, and then, as the disease declines, the secretion increases again, becomes excessively copious, exceedingly viscid, perhaps offensive, and then again it gradually lessens. If the inflammation be not intense, the secretion remains mucous; although it may be altered in its quality, may be diseased, still it is mucous. If, however, the inflammation be more intense than that, the secretion becomes puriform, and a still higher degree of intensity will give rise to absolute pus—purulent discharge. All this you see in inflam-

mation of the urethra, where inflammation is far more violent than that which occurs in the nose. The inflammation of catarrh generally produces nothing more than mucus; but the inflammation of severe gonorrhœa is so violent as to cause the formation of pus. If, however, the inflammation be still more violent than that which occurs in purulent gonorrhœa, you may not have simply pus produced, but fibrin will be poured out. One of the most violent inflammations of a mucous membrane is the crop of children; and in that, the mucous membrane pours forth fibrin, so that the parts become obstructed, and a tube of new secretion is produced. I have seen the same occur in the urethra, where an individual, in consequence of a violent gonorrhœa, has used strong injections, the result of which was the excitement of a dreadful inflammation. Pus had been secreted before, but now fibrin; and a portion of fibrin was discharged from the urethra, exactly resembling an earth-worm in appearance, except in colour.

Occasionally, when mucous membranes are inflamed, hæmorrhage takes place from them; they become so overloaded with blood that the vessels allow its escape, and a hæmorrhage ensues. This is more particularly the case with inflammation of the mucous membrane of the intestines and of the urethra. These membranes more frequently discharge blood when they are inflamed, I think, than any other mucous membranes. Occasionally (but this is a more rare circumstance than the former) inflammation of the mucous membranes induces mortification, or sloughing; this is particularly observed in the throat. Now and then you have ulceration, and this generally occurs in the throat and intestines; it often takes place from the very beginning, and is not at all in proportion to the degree of inflammation. There often appears to be a strong disposition to ulceration. Inflammation of a mucous membrane frequently degenerates into a state of chronic discharge, so that when the inflammation is over, the part continues to pour forth a quantity of fluid, without pain and without heat. This particularly occurs when a mucous membrane has been inflamed several times; and we especially notice this gleet, as it is termed, from the bronchiæ and the urethra. The latter is every day seen in young men, and the former in those who are old. Hence we have *catarrhus senilis*—a gleet, a constant discharge from the mucous membrane of the air-passages, without any inflammation.

If we examine these membranes after death, when they have been inflamed, we find them thicker and softer than natural. If the inflammation have continued very long, they will frequently become very soft and very thin; but, on the other hand, just the reverse is frequently observed. If in-

flammation have induced softening, you may rub them off from the cellular membrane beneath, with the finger. Sometimes, however, these mucous membranes become indurated. It is no proof, if you find a mucous membrane soft, as you frequently do in the case of the stomach—it is no proof that it has been inflamed. I believe that a part will occasionally become softened without any inflammation; at least I know that the softening is frequently out of proportion to any inflammation that existed. Generally, when a mucous membrane has suffered acute inflammation, it is found to be thicker and softer than natural; it is much more rare to find it hardened. The usual effect of acute inflammation is to soften parts; but if, by chance, it should occasion a deposition of fibrin, though it has itself a tendency to induce softening, yet the lymph so poured forth being hard, will cause an appearance of induration. Baron Dupuytren, the eminent French surgeon, and Dr. Thomson, of Edinburgh, found inflamed arteries softened; and the stomach, the bronchiæ, and the heart, when inflamed, are continually found soft. This is the more general effect, therefore, of acute inflammation of mucous membranes.

Sometimes, when a mucous membrane has been severely inflamed, you will find it almost perfectly black. Through the mere congestion of blood you will find it look dark, as if it were mortified; but, on handling it, you find it not lacerable, like a mortified part—you find it still pretty firm and solid generally, and devoid of fætor. Great mistakes have been continually made in the inspection of bodies. After inflammation of the intestines, you often find portions of them almost as black as your hat, without any particle of mortification; and frequently such cases have been pronounced at once mortification of the intestines. Mere congestion of blood will make a mucous membrane almost black, as is seen in the case of the genital organs of rabbits during heat. You will find the error to which I have alluded pointed out by Dr. Baillie in his *Morbid Anatomy*.

It is a general remark that the feverishness, the pyrexia attending the inflammation of a mucous membrane, is comparatively mild. The pulse is generally soft, although it is quickened; and the more frequent the attacks of inflammation in any individual mucous membrane, the more mild they are, and the more early and profuse is the discharge.

Serous Membranes.

If the part inflamed be a serous membrane, such as the arachnoid, the pleura, the pericardium, the peritoneum, or the tunica vaginalis, the pain is for the most part acute, darting, lancinating. The pulse is not soft, as in the case of inflammation of a mucous membrane, but is generally hard, though by

no means always. It is a general but not universal remark, that the pulse is hard. The inflammation causes here, not a secretion of mucus, but a copious effusion of serum, which is sometimes limpid, clear, of a lemon colour; but generally it is turbid, except, perhaps, in inflammation of the head. The serous collection is generally turbid and yellowish, like whey; and sometimes it is puriform. The fluid, in many portions, resembles pus, although other portions of it may be more like serum. Sometimes, however, absolute pus is produced; so that the pericardium has been seen filled with pus. Not only is serum effused, but fibrin is likewise poured forth, the appearance of which is very various. Sometimes it forms a jelly-like yellowish mass; sometimes minute shreds or flakes are seen swimming about the fluid; and sometimes it forms regular layers, looking like so much skin. These deposits of fibrin will at length grow vascular, and when vascular they will adhere to the surrounding serous membrane, and at last become thin again, and in all respects resemble cellular membrane; and hence they have been frequently called *false membranes*. A false membrane is nothing more than an effusion of lymph originally, which has become vascular and adherent to the surrounding serous membrane from which it has been poured forth, and then become, in all respects, like cellular membrane.

This effusion is undoubtedly fibrin. Some have thought it to be one thing, and some another; but, in an article contained in the twelfth volume of the *Medico-Chirurgical Transactions*, Mr. Dowler shews it to be fibrin. I never had any doubt upon this subject, and many persons coincided with me in opinion; however, Mr. Dowler has brought forward evidence in proof of it. You will find it stated, in Andral's *Morbid Anatomy*, that Lassaigne, a French writer, has also ascertained the same circumstance experimentally.

In this deposition of fibrin you will find two portions—one solid and the other fluid. The solid is fibrin itself; but within the various portions of the solid mass, between the layers, or, more properly speaking, in cells, is found a fluid which is ascertained to be albumen. When these depositions have become adherent, they may be injected from the surrounding parts; but, as I mentioned with respect to a coagulum of blood, that it has been seen to have vessels of its own, independently of its connexion with the surrounding vessels—although such vessels become at last connected with those that surround them—just in the same way these depositions of fibrin will, before they are adherent to the surrounding serous membrane, become vascular; vessels will form in them, and within them there has been found even pus, while they were still unconnected with the sur-

rounding parts. Andral says that he has distinctly found a fibrinous concretion swimming in liquid unconnected with the surrounding parts, in a serous cavity; and frequently, even in such as these, he has found pus. It is said that the circulation within these parts is of three kinds. When they are first formed, currents take place in the interstices, through irregular areolæ; in the next place, insulated vessels are found; and, thirdly, these vessels at last become continuous with those of the neighbouring parts; and Andral says that each of these stages may exist in different parts of the same fibrine.

I may mention, that when you open a serous membrane which has been inflamed, you will find upon it points, or stars, or patches of vascular redness. In the first degree of inflammation there are merely points; if there be still more, there are stars; but if there be a still higher degree, and very numerous vessels contain blood, then you have a diffused redness.

Cellular Membrane and Substance of Viscera.

When the part inflamed is either the cellular membrane or the substance of organs—as, for instance, the liver—the pain is fixed; not diffused, as in the case of a mucous membrane, but fixed and rather acute, but not so acute as in an inflamed serous membrane. It is rather dull, but rather acute notwithstanding, and even pulsating, or throbbing. There is an effusion of serum into the surrounding parts, and at length suppuration takes place in that spot where the inflammation is most intense; and in the midst of lymph an abscess is formed, such as I have previously mentioned. If any tumor be produced, you find it hard, and, of course, when it suppurates it becomes soft, and the pain remits, though, generally, the tension from the collection of matter keeps up the pain and the other symptoms. When the matter escapes, the part heals by granulation and cicatrization, as I mentioned when speaking of abscesses.

Now inflammation of the substance of the viscera, or of any part of the cellular membrane forming an abscess, rarely ends in gangrene, except that particular form which is called *carbuncle*. The inflammation of the cellular membrane, or substance of the viscera, is called *phlegmon*; when, however, it is near the surface, and has a tendency to produce gangrene, it loses that name, and we call it carbuncle. In carbuncle, the cellular membrane will die to such an extent, that surgical aid is necessary, in order to make a very large opening for its escape.

Inflammation of the cellular membrane and of the viscera is sometimes not insulated, but diffused, and, as I mentioned, when speaking of the skin, this is frequently called

erysipelas phlegmonoides—provided the skin is also inflamed, or *diffused inflammation of the cellular membrane*, if the skin is not inflamed.

This inflammation is occasionally chronic. Nothing is more common than for inflammation of a mucous membrane to be chronic: but this inflammation is not so frequently chronic, though sometimes it is, and we observe this especially in the lungs and liver, so that people labour under chronic peripneumonia, and more frequently under chronic hepatitis.

Fibrous Membranes.

With respect to the fibrous membranes, this name is given to fascia, aponeurosis, tendons and their sheaths, ligaments, and periosteum. If these be inflamed, the common disease which exists is rheumatism. You may, of course, have inflammation of any of these parts without rheumatism; but if there be a general tendency to inflammation of these throughout the body, it is called rheumatism; frequently, however, the inflammation of a single one of these is the same disease. In rheumatism, although the pain is obtuse, yet there is a feeling of tension, and gelatinous exudations take place, something like synovia. This form of inflammation rarely runs on to suppuration; still more rarely, if ever, to mortification. The pyrexia may be out of all proportion to the violence of the local inflammation, and indeed one character of the disease is the occurrence of profuse sweating. In acute rheumatism, you seldom find profuse sweating to be absent, either at one period of the disease or at another. It generally occurs at the commencement of the affection; at any rate, if the patient be kept at all warm, the tendency to it is sure to show itself; and the sweats are frequently of so marked a character, that you can be at no loss instantly to discover their nature. They are usually very sour. This variety of inflammation generally terminates in resolution, or degenerates into the chronic form; perhaps with a chronic collection of gelatinous matter about the joints and in the thecæ of tendons.

The peculiarity of this inflammation is, its great tendency to wander—to *migrate*, as it is said, so that you shall have it now in one joint, and in a few hours in another. Occasionally it is metastatic; it will cease in these particular parts, and inflammation of an internal part will begin, generally an inflammation of some membrane, either the arachnoid, I believe, or the dura mater, we cannot say exactly which; but, certainly, more frequently than not, it is the pleura or the pericardium, the latter, however, more frequently than any other. But it is not by metastasis only that this internal inflammation takes place; for you will continually see inflammation of the pericardium or of the pleura occur in rheumatism, while the affec-

tion is going on in the joints, just as violently as before; and frequently this internal inflammation does not take place till after the rheumatism has been over some time. When the pericardium, for example, has been inflamed, if the person do not die, the pericarditis has a great tendency to become chronic; disease of the heart is then set up; the substance of the heart itself frequently becomes thickened, or hardened, or softened; the internal membrane of the heart, chiefly about the valves, becomes affected, and you have all the symptoms of a diseased heart: you have organic disease of the heart established. This is by far the most common origin of diseased heart in young persons. Pericarditis is first set up, and this pericarditis is generally connected with rheumatism.

Such are the chief varieties of inflammation occasioned by structure.

Inflammation.—Varieties in the Symptoms of Inflammation from Sympathy.

The sympathies of the particular part affected likewise occasions varieties in the general symptoms. You have some symptoms from the sympathies of the *general* structure affected: for example, if the structure affected be a serous membrane, from its sympathies you have a peculiar pulse; in general, a hard pulse. From another sympathy, when fibrous membranes are affected, you have a particular sweating. But, besides these general sympathetic effects—these effects from a particular structure, you have peculiar sympathetic effects from the *organ* itself, to say nothing of its structure. When the stomach or intestines are inflamed, you have generally a sensation of great weakness and a wiry pulse; but this does not occur as the consequence of an inflammation of the peritoneal coat of the intestines, or any other of their coats, for then it would take place when a similar structure was inflamed in other parts, but it occurs because the organ affected is the *intestines* or *stomach*. When the kidney is inflamed, you have vomiting, a retraction of the testis of the same side, and various other symptoms, simply because the *kidney* is inflamed. Hence you have a certain set of symptoms in inflammation from the peculiar sympathy of other organs with the part affected.

There are other varieties also observed. Erysipelas of the head has a great tendency to run to the brain. One can hardly say this is metastasis, because the inflammation frequently continues violent in the face itself, when the symptoms of phrenitis come on. Inflammation of the parotid glands of that peculiar kind said to be contagious, called *mumps*, has a great disposition to occasion sympathetic inflammation of the brain or of the testes. Indeed, when any organ is inflamed, and the inflammation continues any length of time, it is not uncommon for ano-

ther and a distant organ to become inflamed likewise; and these organs are generally either the brain, the lungs, or the alimentary canal; sometimes however the skin, and sometimes the throat, but more frequently the brain, the lungs, or the alimentary canal. When a part has been itself once inflamed, it has a great tendency to fall into inflammation again from slight causes. You certainly have inflammation of an organ from sympathy with the particular organ affected; and very frequently when this second inflammation occurs, although it may be very slight, it is attended with very considerable ill effects; the constitution is so much impaired by the first inflammation, that the addition of disease in another organ produces, though slight, very great danger, and frequently death.

Intermittent Inflammation.

Inflammation is sometimes intermittent, and sometimes absolutely periodical. Inflammation of the eye has been observed to recur at particular periods; it has frequently been observed to be intermittent—to come on violently every evening, or every other evening, at a certain hour: I have seen periodical catarrh.

You will have variations of inflammation according as the constitution is healthy or unhealthy. If the constitution be healthy, the inflammation is more active—is more rapid, and the terminations, when they occur, are more perfect. When the constitution is in an unhealthy state, the parts inflamed are feeble; there is less activity of the inflammation, less brightness of colour; the terminations which take place are less perfect, and the secretions of the part are more unhealthy.

Specific Inflammation.

You have still farther varieties in the symptoms of inflammation, according to the cause which has produced it, and the inflammation on this account is frequently termed *specific*; for example, inflammation of the skin, as in small-pox, is induced by a specific cause, and therefore it is called a specific inflammation. Independently of its cause, some inflammations run a peculiar course, and are therefore specific: such is erysipelas.

PASSIVE INFLAMMATION.

I have been considering active inflammation, but inflammation is said also to be passive. If in an inflammation there be but little pain—if the redness be dull—if the heat be but slightly increased, perhaps not at all—if there be more than the usual swelling, and a very abundant secretion, the inflammation is said to be passive. I have already mentioned that some persons object to this term, and say that such a set of symptoms as these are not inflammation; and

Andral, to avoid the difficulty, calls all inflammations and congestions hyperemy—the excessive presence of blood in the part. Active hyperemy is synonymous with active inflammation; whereas, if the symptoms be those I have just described—a dingy colour, flaccidity of the parts, little or no pain—then, instead of calling it passive inflammation, which he says is absurd, he calls it passive hyperemy.

Acute and Chronic.

The terms acute and chronic apply merely to the duration of inflammation, and not to the difference as to whether it is active or passive. An acute inflammation may be at first passive. When a person is already weak before the attack of inflammation, or the part has been frequently inflamed before, then at the very outset the inflammation may be of a passive character, although acute. After inflammation has continued for a length of time, it may be still active, the part may still be hot and painful, and the state may yield only to the remedies of active inflammation. Hence active and passive with regard to inflammation, as with respect to all other diseases, are not synonymous terms with acute and chronic.

Tonic and Atonic.

You will find inflammation sometimes distinguished into tonic and atonic; and these terms refer not to the active or passive condition of the part, but to the powers of the system. If the constitution be strong, the inflammation is called tonic; whereas, if the system be in a weak state, the inflammation is called atonic, because inflammation is sometimes very violent in part, and yet there is no power, the activity is all of short duration, the powers are exhausted, and perhaps mortification takes place. The activity—the violence of inflammation in a part—is more than commensurate with the powers of the system. If the part be in a state of activity, the inflammation is called active, but if not, it is called passive; whereas, the words atonic and tonic rather refer to the powers of the system at large.

Effects of Inflammation on Structure.

Now inflammation, when it continues, will cause an enlargement of parts; it will cause them to increase—to be over-nourished, and then the occurrence is termed hypertrophy—excessive nourishment. On the other hand, it will cause them to waste—to be under-nourished, if I may so speak, and then it is called atrophy. It will occasion them to be indurated, to be softened, and it will give rise to various transformations, so that a part shall become pretty firm cartilage, or actual bone. These results of inflammation are sometimes combined in the same part, so that a part shall be both hypertrophied and atrophied. If a part be compounded of dif-

ferent structures, one structure may increase, become harder and thicker than before, while another constituent of the same organ shall waste away; and one part shall become indurated while another shall become softened, so that you may have hypertrophy and atrophy—induration and softening—in different structures of the same compound organ. For example, you frequently see a thickening of the investing membrane of an organ, and a wasting of the substance of the organ itself; you will sometimes see a thickening of the cellular membrane, while one of the other structures shall waste away. The retina is sometimes found in a state of atrophy, while other portions of the eye are excessively thick, or indurated to cartilage. Acute inflammation more frequently, as I have already said, causes softening than hardening; and wasting rather follows acute inflammation than chronic, excepting when the chronic form induces such over-nourishment of one constituent part of an organ that another structure wastes. Generally, however, acute inflammation is disposed to produce softening; and if any other change occur, it is rather that of atrophy. Chronic inflammation, on the other hand, chiefly causes parts to become hard, and hypertrophied, over-nourished, thickened; and it is this which causes transformations—causes parts to become cartilage or bone. I do not mean to say that these will not arise without inflammation; but when they are produced by inflammation, it is usually the chronic and not the acute form which gives rise to them.

Analogous and Non-analogous Transformations.

Besides, however, these alterations of structure with regard to size and consistency, and these changes to a new structure, but still a structure which exists in the body, you will find parts which have been inflamed acquire a perfectly new character, and form a structure unknown to the healthy body. If the changes of structure be merely to bone, or cartilage, structures which exist naturally in some parts of the body, then the formation is called *analogous*—that is to say, it is analogous to a structure of the body; but if the change of structure produced do not naturally exist in the body, then it is called *non-analogous*. The same occurrence takes place with respect to the fluids which are poured forth in inflammation. Serum, fibrin, and mucus, which are occasionally poured forth in an increased quantity in inflammation, are analogous to what exist in the body naturally; but that is not the case with pus, and consequently it is non-analogous. You therefore see, that in the case of both the fluids and the solids, the results of inflammation are similar,—the productions may be analogous to what occur in the body, or they may be non-analogous.

Now it is to be remembered, that these

CLINICAL LECTURES,

Delivered in the Dispensary of the London University,

By DR. ANTHONY TODD THOMSON.

LECTURE VII.—Nov. 29, 1831.

Melancholia—Chorea—Epilepsy.

various changes of size—hypertrophy and atrophy; of consistency—induration and softening; as also these transformations; the occurrence of hæmorrhage, the occurrence of effusion,—dropsy, the occurrence of a discharge from a mucous membrane—a gleet, and perhaps adhesion, ulceration, and mortification—nay, even some say suppuration—may take place without any inflammation. They are continually the effect of inflammation; but certainly most of them do sometimes occur without our being able to discover that any inflammation existed. In the case of hæmorrhage, though it is frequently the result of an active inflammation, and generally too in a mucous membrane, yet it is often passive, and is poured forth without either pain, heat, swelling, or general irritation—nay, it is frequently poured forth without any fulness at all to be discovered in the vessels of the part. I have opened persons who have died from hæmorrhage, in whom there was no collection of blood to be found in the parts which afforded the hæmorrhage. While every part of the body from the head to the foot was perfectly pale, yet there was hæmorrhage from time to time until death ensued; and it must have come from small vessels, because no large vessels could be discovered ruptured. Certainly you will have chronic hydro-thorax and ascites without any inflammation of the serous membrane—no pleuritis, no peritonitis. With respect to mucous membranes, you continually see a gleet without the occurrence of any one symptom of inflammation. It is even thought by some, that suppuration of the lungs will take place without inflammation—that where a single romica of mere tubercular matter has been generated, and suppuration has taken place, there has often been no previous inflammation. Whether that is correct, I will not say; but certainly large adhesions continually occur in the pleura, in persons who have no recollection of having been the subjects of inflammation within the chest. Occasionally portions of fibrin are spit up from the bronchial tubes, without a person having beforehand suspected the slightest inflammatory state of those parts. Ulceration is thought by some surgeons to occur occasionally in the cartilages of joints without inflammation; and certainly ulceration will now and then take place in the skin and throat, with little or no inflammation. Such ulceration is continually seen in scurvy: ulcerated, like softened, mucous membranes, are sometimes quite pale. Mortification will occur every day without inflammation. Instances of this are seen in the lungs, and more rarely in other viscera. It will also occur in the extremities, from bad food, and more especially from that description called *ergot of rye*. But I must resume this subject at the next lecture.

GENTLEMEN,—The case of Melancholia to which I alluded in my last lecture, and which is still under treatment, has afforded you an excellent opportunity of observing the characters of that disease. It is one which seldom presents itself in the practice of a Dispensary. I will first read to you the successive reports subsequent to that of the 17th, up to which point they have been already given; and then offer you a few remarks on the general nature of the disease, its causes, and its probable termination.

On the 22d—the patient, Ann Rooke, stated, that her melancholy feelings and forebodings of evil were rather worse than better; but that she had slept well on Sunday night after the dose of the Tincture of Foxglove was increased. On examining the pulse, the system appeared to be under the sedative influence of the Foxglove. She, however, still suffered from pain at the occiput; the bowels were open, the motions dark, and the urine also was scanty and high coloured; the tongue was, as before, furred, and studded with red papillæ. She was ordered the following mixture:—

R Tincturæ Digitalis, ℥i. xl.

— Hyosciami, ʒij.

Infusi Calumbæ, f. ʒjss. M. Suman-
tur Cochli. iij. majora 8va. quæque
horâ.

She was also directed to take at bed-time, nightly, gr. xij. of Camphor, and gr. iv. of Extract of Henbane.

On the 24th, the report is—Has not been so sick, although the nausea continues. She has slept better for these two last nights, but still complains much of her head, with a creeping sensation over the body, great languor, and the same confusion of ideas and despondency as before—that is, of a constant apprehension of death. She also speaks of an uneasy sensation at the chest until she takes food; yet the appetite is indifferent. She has no religious misgivings to alarm her. The tongue is rather cleaner; the pulse small and quick; the alvine discharges are still dark and offensive. The pills, with Camphor and Henbane, were desired to be continued, the mixture with the Foxglove omitted, and the following mixture to be taken in its stead:—

R Animonii Tartarizati, gr. vj.

Aquæ Distillatæ, f. ʒvj. M. Pars 4ta,
primo mane, quotidie, sumenda.

On the 26th she stated that her anguish of mind was greater than ever, and occasionally despair took possession of her; her sleep was also more disturbed by frightful dreams. She admitted, however, that she was daily more comfortable, in the mornings, as long as the vomiting and sickness caused by the mixture lasted. The Antimonial mixture, besides vomiting, purged her freely; the stools were still dark and offensive, and the urine was high coloured; the pulse small, but less frequent and more regular, and the tongue as before.

She complained of continual restlessness, and a desire to move from place to place.

To-day, 29th, she says she feels much better; and although she is still haunted by horrifying thoughts, yet, she has slept better for three successive nights. Her bowels are now rather costive; she has been ordered to take a brisk purgative, and to continue the use of the Antimonial mixture and the Aodyne pills.

Such, gentlemen, is the state of this poor woman at this time. There is no doubt that her disease is *Melancholia*, a variety of Insanity, which has, in many respects, a close similitude to *Hypochondriasis*; but which, requiring a different mode of treatment, is necessary to be distinguished from it. Let us examine, therefore, in the first place, the circumstances which enable us confidently to pronounce this case to be one of *Melancholia*: they are these. In the history of the case, we find, that, at the time the patient was attacked, she was in good health; that her spirits became suddenly depressed from some family matters, and she has since been utterly uncomfortable in her mind. This, therefore, is one of the circumstances which determines the disease to be *Melancholia*; the attack was sudden, the exciting cause a mental one, and there were no premonitory symptoms of *Dyspepsia*, which always precede attacks of *Hypochondriasis*. And here let me impress upon you, gentlemen, the importance, in your inquiries after causes, to ascertain accurately the state of the patient previous to the attack, as it is only by doing so that you will be enabled to form a correct opinion of the changes which the morbid causes have produced in him. In the second place, the symptoms of the case before us are, various phenomena of *despondency* and *despair*; the patient merely says that she "is uncomfortable in mind;" it is only by a kind of cross-examination that we discover the existence of the cerebral and gastric symptoms; whereas, in *Hypochondriasis*, the mental phenomena consist, almost wholly, of erroneous ideas of the corporeal health, or of the make or the body of the patient. It is, however, necessary that you should be made aware that the absence of dyspeptic symptoms is not essential, in a case of *Melancholia*; and, although they have

not displayed themselves in the instance, before us, yet, it sometimes happens that the symptoms of both diseases are seen in the same person. At one time, the illusions of *Hypochondriasis* prevailing, at another time the despondency and despair of *Melancholia*. In such a case the attack is still to be regarded as the latter malady, and treated as such. In the third place, we are guided in our diagnosis also, in some respects, by observing the predisposition of the patient to the disease, as indicated by those appearances which are admitted as characterizing the melancholic temperament—which are, a lean and dry frame of body, small and rigid muscles, deep black hair, a pale sallow complexion, the eyes sunk in their sockets, with large veins, denoting, as Cullen would express himself, a balance of the sanguiferous system upon the side of the veins, with a constant expression of anxiety and dejection. With such a tendency to the disease—when sudden or violent, and especially painful domestic changes, or other causes of grief or despondency occur, then *Melancholia* rapidly displays itself.

This disease, like many others, shews itself in various forms. In the present instance, the constant restlessness, and desire for a change of place, arranges our case under that variety which has been termed *irrabunda*, or *Restless Melancholy*. In endeavouring to account for the corporeal symptoms, it is necessary to take into consideration the effect of the depressing passions upon the body, in producing a torpor in almost every irritable part; thence the paleness of the countenance, the contraction of the features, the sensation of languor and coldness of the extremities. To the same cause also is to be attributed the feeling of anxiety and oppression at the chest, and the sensation of a fulness at the heart, as if it would almost burst—a feeling which you will find very often expressed by melancholic patients. The sighing that accompanies this state of the circulation is an effort of nature to restore the ordinary pulmonary circulation, and to promote that due change in the blood which is retarded in *Melancholia*. It is not difficult to account for the languor always more or less accompanying *Melancholia*. Sudden grief often operates on the system as a powerful sedative; the corporeal strength of the patient appears suddenly to leave him; his knees tremble; the muscular power of the limbs seems to fail; and in some instances he falls to the ground in a state of syncope. When the mental impression, however, is less powerful, no sudden effect of this kind takes place; but corporeal symptoms are gradually induced, some of which are present in the case before us. Thus we find such an irritable state of stomach, that, along with a sensation of pain in it, there is occasional vomiting after taking

food, which would almost lead to the belief of the existence of inflammation in the stomach; this symptom is more common in females than in males. The load of blood which is thrown upon the liver readily explains the condition of the biliary secretion: as in our case, it is changed in colour and in consistence; and it is highly probable that, although this depraved state of the bile is evidently the effect of the unhealthy condition of the brain, yet to it may be attributed many of the other symptoms—the irregular action of the intestines, the flatulence, and the faulty state of the digestive organs which sometimes accompanies the mental dejection. The headache is generally regarded as altogether sympathetic; but, in the case before us, we might suspect some obscure inflammatory state of the cerebellum, as the acuteness of the pain referred to the occiput can scarcely be accounted for on any other supposition. If this opinion were correct, it might be asked, are not the symptoms, as connected with such a state of the cerebellum, at complete variance with the doctrines of phrenology? But this is a part of the subject which I confess my inability to discuss; and I must also admit, that there is no demonstrative proof of such a state of the cerebellum, which is only presumed from the acute pain at the occiput. It is also true, that lunatics have expired with symptoms indicating affections of the brain; and yet, on dissection, the keenest eye has not been able to discover any appearance that could explain them. There is another physiognomical characteristic of this affection, which, although unnoticed in the reports, yet is present in the case under treatment, and must have struck you—I mean the expression of frowning, which the drawing together of the eyebrows never fails to produce, when the attention of the patient, as is generally the case, is absorbed with the prevailing idea which fills the mind. It is the despotic ascendancy of this prevailing idea also over the mind, becoming an habitual subject of nocturnal meditation, which is the cause of the obstinate watchfulness that always accompanies this form of Melancholia. The idea which, in the case before us, overshadows the enjoyments of life, is not unfrequent; and what may appear remarkable, this very dread of dissolution has driven the wretched sufferers into the arms of that awful being, whose imaginary advance embitters every moment of their existence. Such is the brief view of the *ratio symptomatum* which I have to present to you; and it will not be out of place, even whilst the case is under treatment, to mention the usual terminations of this variety of Insanity.

The usual termination of Melancholia, when it is not averted by medical treatment, is either in a state of mild, or of furious delirium or mania, or of despair. In which of

these states a case of Melancholia is likely to terminate, may in some degree be foretold from a knowledge of the natural disposition of the individual. The first state is most likely to occur in habits endowed with the power of patiently sustaining pain, whether corporeal or mental; the second and the third, in those in whom, from the structure of the nervous system, any description of pain cannot be long borne without exciting an increased arterial action in the brain. Of these three terminations the most common is that of despair.

It is only by reflecting upon the many painful feelings, both corporeal and mental, constantly preying upon the wretched subject of Melancholia, that can afford you any accurate idea of the real origin of despair in these cases. The sense of moral duty and of religious obligation, however strong its influence may have been in regulating the conduct of the sufferer before his attack, is gradually weakened by the contemplation of the wretched prospect which appears to surround him on every side; he discerns nothing but a dreary and comfortless desert, without a single oasis to refresh the mind or admit of even a momentary feeling of enjoyment. Restless, anticipating no respite from bodily and mental suffering—tired out—hopeless—the victim of despair can perceive no prospect of relief from his sufferings but in the grave; and he resolves on suicide, not so much from the desire of death as of rest. On the one hand, he sees in every object only the misery of life; whilst, on the other, he believes that he can obtain relief by withdrawing himself from it. He is incapable of exercising a correct judgment; and, tired out with the buffetings of the storm, he seeks the only port in which he conceives shelter is to be found—the quiet of the grave. The beauty and truth with which this feeling is depicted in Lord Byron's poem of the Giaour, will, I am certain, plead my excuse for quoting a passage from it.

“Waste not thine orison—Despair
Is mightier than thy pious prayer.
I would not, if I might, be blest—
I want no paradise—but rest.”

Such is that state of mind which leads the victim of despair to form the resolution of suicide; and you have more than once, gentlemen, heard our unfortunate patient declare, that ideas have passed through her mind “that make her shudder even to look back upon them.”

With regard to the treatment of this case, you perceive, gentlemen, that although I think it possible that a low degree of sub-acute inflammatory action may exist in the cerebellum or its membranes, yet I have not ordered blood letting either general or local. I wish to direct your attention to this circumstance, to impress on your minds the

fact, that insanity always more or less implies debility; indeed, the general appearance of the patient, the absence of any thing like acute symptoms, and the feeble beat of the pulse, render general bleeding inadmissible; and as there is neither turgescence of countenance, nor sense of heat in the scalp, nor noise in the head, I have felt disposed rather to trust to the effects of emetics and purgatives, than to abstract blood even locally.

Emetics are very generally employed in the acute form of Insanity; and, in Melancholia, when the constitution of the patient is unimpaired by intemperance—when the torpor of the liver and alimentary canal indicates oppression rather than exhaustion of the vital powers, as in Rooke, I am of opinion that the excitement given to the stomach by a moderate dose of Tartar Emetic, operating in some measure as a counter-irritant, is always beneficial. In this case, the daily repetition of it has been productive of comfort to the patient, whose mental feelings continue calm and undisturbed as long as the sickness and vomiting continue. It is not uncommon to combine emetics with purgatives; but in the present case the Tartar Emetic has both evacuated the stomach and the bowels, and has rendered such a combination unnecessary. I have considered it also advisable to administer a narcotic in the evening, and the emetic in the morning, not merely with the view of procuring sleep, but to insure the emetic influence of a small dose of the Antimonial; for I have had many opportunities of verifying the remark of Dr. Cox, that one-third of the usual dose of Tartar Emetic is sufficient when a narcotic has been taken on the previous night, and a better effect has followed than when no such precursor had led the way. The purgatives which had been previously administered, and which are always indicated by the torpid state of the bowels, in this variety of insanity, were continued as long as the nature of the evacuations required their employment; and I was desirous, by their means, to remove any congestion that might have existed before the use of the emetics was commenced. The continuance of the purgatives longer might have too much reduced the strength, whereas the emetics have had no such effect; the pulse is much slower, but at the same time it has filled, and has become more regular than before their commencement. It is true that Melancholia is what is termed an asthenic disease; but it is also one that is never benefited by tonic or stimulant remedies.

The constant watchfulness, and the necessity of procuring repose in every form of Insanity, are obvious; the only difficulty is in determining which of the narcotics ought to be employed. In acute Mania, digitalis effectually assists in reducing the furor, and promoting refreshing sleep, after the lancet and purgatives have been freely employed.

In Melancholia, such a previous reduction of excitement is not generally requisite. The Tincture may be administered at the outset; and on this account it was ordered the first day that I saw the patient, but its effects did not permit it to be continued, even after the dose had been reduced to forty minims in the twenty-four hours; a result which can only be referred to idiosyncrasy. I am, indeed, most anxious to impress upon your minds the fact, that Digitalis is not a direct sedative; its first action is decidedly stimulant, and, like all other narcotics, it depresses exactly in the ratio of its previous excitement. Wherever strong arterial action exists, its hurtful effects are almost instantaneously perceived; thence the necessity of reducing the force of the pulse previous to its employment; and, when this has been attended to, its calming and soporific effects are certain. You should, however, be made aware that, in Melancholia, the sedative or debilitating influence of Digitalis should be narrowly watched; for, if admitted to proceed beyond a certain point, a morbid action is readily induced, and congestion is the consequence. In Melancholia, opium is, undoubtedly, a hazardous narcotic; not less because of its tendency to produce over-distention of the cerebral vessels, than on account of the torpor of bowels which usually succeeds its use. There is much less objection to Camphor, which somewhat resembles Foxglove in its mode of operating; but when its use has been continued for some days, and, after acting as an anodyne, its effects begin to be perceived on the countenance, inducing pallor and lividity; and when the extremities become cold and insensible, its further employment would only be productive of much mischief—congestion of the lungs, suspension of the power of the heart, and general torpor of the system. In the present instance, its conjunction with Hyoscyamus has answered well.

I should now, gentlemen, proceed to give you some idea of the moral management necessary in Melancholia; but I will reserve what I have to say on this part of my subject until the termination of the case before us, and at present only remark, that the nature of the moral treatment must depend greatly on the prior mental habits or propensities of the patient. The circumstances under which patients are attended at Dispensaries are unfavourable to the moral treatment of the disease; and, although the condition of the poor, and the constraint of labour which necessity imposes, generally secures them from feeling the burthen of *ennui*, and suffering from a refined sensibility, yet, when they are too ill to follow their ordinary occupations, the general vacuity of their minds tends to aggravate the excess of their sufferings, owing to their attention being wholly absorbed in them.

Chorea.

The girl who was labouring under this disease is convalescent, the irregular movements having gradually yielded to the influence of the purgatives and the carbonate of iron.

Epilepsy.

Leni has continued free from any return of the fits, but to-day he experienced something like a threatening of them; for instance, in the morning he felt giddiness and temporary dimness of sight, with great confusion of intellect, which continued for nearly two hours, during which time he heard the voices of those who spoke to him, but was unconscious of the nature of the subject of their discourse. As this state declined, he felt cold, and experienced a rigor. The pulse is small and irritable; the tongue furred; the urine natural; and the bowels are open.

He has been ordered to take directly a brisk cathartic; to have a seton introduced into the nape of the neck; and to take a pill, containing gr. v. of the oxide of zinc, three times a day.

CHARACTER AND TREATMENT OF CHOLERA.

By C. NEGRI, M.D.

[Continued from the preceding Number, p. 351.]

As my object throughout the preceding letter has been to direct the attention of the Medical Board to facts, statements, and authorities, which did not appear to me to have received sufficient notice, I have refrained from encumbering the narrative with any observations of my own, either by way of corroboration or of commentary. But as Torti's views on this subject are not generally known in this country, I may, perhaps, be excused for laying this letter before the profession with a few explanatory remarks. I am not ignorant that some writers of the present day have taken a very similar view of the nature, and have proposed a very similar treatment, for the cure of malignant cholera with those which I have now been giving. I am aware that Mr. Searle's theory of this disease is not essentially different from that entertained by Torti, and I believe that had he known Torti's works on Pernicious Fever, he would have acquiesced in most of the sentiments of that author. Mr. Searle notices the great resemblance of malignant cholera to

intermittent fever; but speaking of the stage of re-action, he compares it to the congestive typhus of this country. Not having yet witnessed any cases of malignant cholera, I cannot positively object to the justice of this comparison; but I am quite certain that these pernicious fevers differ from the congestive fever of England in more respects than one. The pernicious fever seizes the patient suddenly, when in apparent health; it more or less assumes the intermittent form, the intermission varying, however, very much in length, and occasionally being so incomplete as to be almost imperceptible; it seldom presents at any periods of its course symptoms of re-action; it is uniformly fatal if left to itself; and, when properly treated, its disappearance is almost quite as rapid as its progress, if neglected. In all these respects, and in others unnecessary to mention, these two affections are essentially different; and I think it will be allowed, that when compared in these points with spasmodic cholera, the *febris perniciosa* of Torti, is not extremely dissimilar. I have seen several cases of this fever, and although their symptoms somewhat varied, their general character is so peculiar, that when it is once witnessed, it can never be again forgotten. It usually commences with the ordinary symptoms of a single tertian or quartan ague in a severe form. The second paroxysm is invariably much more malignant than the first, and the disease is so strengthened at every new fit, that the third or fourth is in general quite sufficient to destroy life, if the proper remedies be not had recourse to. Occasionally it wears the form of a double tertian, or quotidian, with *accessiones subintrantes*, as the old writers would say, and with such imperfect intervals, that its periodical character may be very easily overlooked. There is no subject on which opinion is less divided, at least in Italy, than that of the treatment of these pernicious agues. Since Torti wrote, no one thinks of employing any other remedy, in the first instance, than bark, in large doses; and the only point of difficulty to be considered by the practitioner is the recognition of the disease, for it not unfrequently stands in hazard of being confounded with diseases of a different character. I was in the habit of mixing an ounce of bark with a drachm of laudanum for a dose, which

was given at the first appearance of the disease, and was repeated at intervals, proportioned in length to the intensity of the symptoms. Mr. Annesley, I am aware, has employed bark in India, and Ponpiriff in Orenburg, but rather as a tonic, in the advanced stage, than with any more curative or active view. The sulphate of quinine has also been tried in Petersburg, but with the same view; and Mr. Searle has given this salt with advantage, but towards the close of the disease.

There are several reasons, however, for objecting to the use of this form of the bark, at least in preference to the common powder. In the first place, cinchona, besides a certain quantity of quinine and cinchonine, contains some other principles of an astringent nature, which may render it more suitable for a disease, in which the mucous lining of the alimentary canal is in a state of extreme excitement. Secondly, I apprehend it has not been given in sufficiently large doses, nor early enough in the disease. Lastly, I have tried it, and its success has not been by any means so complete as that which followed the employment of the bark in a simple state.

Towards the close of the summer of 1821, when in Italy, I was requested to see a lady of a delicate constitution, and about 50 years of age. She was labouring under the symptoms of a *febris perniciosa dysenterica quotidiana*;—cold shiverings; profuse evacuations from the bowels; nausea, but not vomiting; tongue pale, but moist; small, weak pulse; cold, clammy perspiration. She was so weak, that *deliquium animi* occurred at almost every stool. Towards evening, these symptoms wholly ceased to re-appear on the following day, with increased severity. After the second fit had made me certainly acquainted with the nature of the malady, I lost no time in having recourse to the bark; but as the sulphate of quinine was then coming into notice, I thought proper to employ it. I do not exactly recollect the dose in which it was exhibited, but it was given in the form of pills, at short intervals. No paroxysm occurred on the day following its first employment, but a fit took place the day after, only in a mitigated form. The simple powder was now substituted for the salt, and the patient was speedily cured.

From the result of its action in this case, together with the reasons above given, I have been induced to suspect, that in cholera, where there are copious evacuations from the bowels, the sulphate of quinine may not only aggravate that symptom, but be carried off before the necessary effect has been produced upon the system. These consequences I do not apprehend from the pure bark, either in the form of powder or tincture; more especially where it is combined with opium or laudanum. The only reasonable objection which occurs to me against its applicability in cholera, is the extreme rapidity of this disease, and the very short period which it allows the practitioner for the employment of any remedy. In many instances, however, its course is less rapid, and I do entertain great hope that it will be found highly beneficial in these, if not in all cases. In this opinion I am the more encouraged since I have read, in the *Morning Herald* of the 1st instant, that Dr. Barry, at the public meeting held on the 26th of October, at Newcastle, admitted that “there was more analogy between it (malignant cholera) and the worst forms of tertian ague, or intermittent fever, than between it and the ordinary cholera of this country.”

To give some idea of the extreme severity of the cases in which Torti successfully employed the bark, I beg leave to condense from that author's work the two following histories of the *febris algida perniciosa*; some points of difference will be discovered between them, but these, in no degree, affect their essential features, which in both are precisely the same. “When I reached the patient, he had been several hours labouring under the disease. I found him universally cold as marble, with the pulse altogether, if I may so say, absent, breathing laboriously, and having a leaden-coloured countenance. There was some torpor, but no confusion of intellect (*he never mentioned delirium*), and his urine was secreted in a small quantity. . . . I prescribed the bark in large doses. A gentle heat soon pervaded his entire frame; the pulse gradually returned; the respiration became natural; the face lost its leaden hue; the urine was secreted in its ordinary quantity, and in three days he was quite recovered.” Lib. iv. cap. iii.

In the second case, Torti found the

patient "quite altered in countenance, and as exhausted in strength as though he had been confined with illness for two months. On endeavouring to take the number of the pulse it could not be perceived; the skin was universally cold as marble; the urine was scanty, but highly coloured; the eyes were vivid, and unusually glistening; there was little thirst, and the mind was quite clear, but depressed; the patient saying, '*jam senti o me mori.*'"—Id. The bark was given in large doses, and at short intervals, in the usual way; every unfavourable symptom gradually declined in a few days, and ultimately vanished. In the fourth book of Torti's work, he relates very many similar and equally interesting histories of this pernicious form of ague; but as we trust enough has been already said to shew the striking resemblance of this affection to malignant cholera, and its perfect manageability under Torti's treatment, we shall leave the profession to peruse the author at their convenience, with this concluding observation—that the circumstance of Torti, Morton, and Mercatus, being somewhat less modern writers than some might wish them, cannot in the least detract from either the value of their experience or the veracity of their testimony. Facts are unchangeable things, which neither time, nor place, nor circumstances, can alter; and, although I do not pretend to say that the oldest writers are the best, much of the value of many of our modern publications, and much of the distinction of many of our living authors, are derived from works and writers now almost equally forgotten.

MALIGNANT EUROPEAN CHOLERA.

To the Editor of the London Medical Gazette.

SIR,

IF you consider the following additional observations worthy of a place in your valuable periodical, I shall be glad to occupy a small space in your next number.

In my letter to you of the 18th instant, I have stated it as the conviction of my mind, that the modified cholera which has appeared on the continent of Europe, is a fever, differing only in de-

gree, and in a very few symptoms, from some other fevers of a malignant nature; but more intent upon the practical application of the doctrine which I had ventured to broach, than upon the establishment of a new theory, I said but little on that part of the subject. That I may not now, however, be suspected of theorising, or of offering opinions without due consideration, I will just mention a few of the opportunities I have had, from my public situation in his Majesty's navy, of seeing and treating various fevers in all parts of the world.

In the winter of 1799, after the disastrous retreat of our army from Holland, an hospital ship was fitted out at Portsmouth for the reception of the sick and wounded Russians, then our allies. In that hospital I had but *too many* opportunities of witnessing typhus fever, in its worst shape; and the opinions I then formed were fully confirmed in the summer of 1801, during my attendance upon upwards of a hundred French prisoners of war, who were sent to our floating hospital, in the river Medway, with malignant typhus. Whilst in charge of his Majesty's Naval Hospital at Madras, I had also an opportunity of witnessing, upon an extensive scale, the fevers peculiar to India, (including dysentery, that greatest scourge of India, until the introduction of cholera.) During a residence of more than ten years in this town, the fenny country in the neighbourhood has been a prolific source of fever, chiefly of the continued, remittent, and intermittent types; for when I state that I have prescribed for fifteen thousand fever patients in that period, I shall be considerably under the truth. Few cases of typhus (and those of a mild kind) have come under my notice; indeed, I am inclined to hope that the malignant typhus, but too frequently met with thirty years ago, is now of rare occurrence, owing, I trust, to better management and free ventilation.

It is my firm opinion, after all that I have read or seen, that the miasm, or poison, producing typhus, malignant European cholera, and intermittent fevers, makes its primary assault upon the "nervous power" in general, and not upon any particular class of nerves; and by its powerfully sedative effect deprives the muscles of the only influ-

ence by which they are enabled to act. Hence the sudden prostration of muscular power, the spasms, &c. The suspension of the "nervous power" also puts a stop to the evolution of caloric from the arterial blood. Hence the sudden coldness of the surface of the body, the blue skin, the diminished capacity of the blood-vessels near the surface, the consequent retreat of the blood into the more sheltered and warmer parts of the body, and the fearful internal congestion, and interrupted function, of the various vital organs. I should also point out the total suspension of the secretions of bile and urine as a consequence of the loss of "nervous power," and which will also serve to strengthen my opinion, that the fluid ejected from the stomach and bowels, in malignant cholera, is not a *secretion*, but a *transudation*, occasioned by the gorged state of the vessels of the stomach and intestines: at all events, it does not resemble any known secretion of the human body, and I am disposed to attribute its presence rather to the cause above-mentioned than to consider it as a secretion occasioned by the introduction of the poison of cholera into the alimentary canal. I have been the more particular on this point, because some practitioners have considered this harmless fluid as being of an acrid, irritating nature, and consequently have recommended it to be purged off, an error which I consider would be fatal in the exhausted state of the patient; indeed, purgatives are out of the question, in my opinion, until re-action has been *completely* established. Some of your correspondents are of opinion, I perceive, that the poison of cholera vitiates the whole mass of blood; but I think the interruption given to the healthy function of the lungs, together with the diminished heat of the body, will satisfactorily account for the dark and thick state of the blood, without the actual introduction of the virus into the circulation.

This theory, of which I have attempted to give a brief outline, appears to me to explain, in the most satisfactory manner, the phenomena attending the attack of malignant cholera. There is one striking difference between the attacks of typhus and cholera: in the former the "sensorial," as well as the "nervous" power, is laid prostrate, whereas in the latter, the "sensorial

power" is little, if at all, affected. This fact, I think, proves pretty clearly that these two fevers arise from different poisons. Were it not for the acknowledged fact of the non-contagious nature of intermittent, I should say that I have seen (in this country) no disease so nearly resembling the cold stage of cholera as the cold stage of severe intermittent.

With respect to the treatment of cholera, I would strongly recommend the plan proposed in my last letter. In severe cases, where the heat of the body cannot be restored by the hot air-bath, I trust that galvanism will be found a most powerful auxiliary, by restoring the *vital action*, through which caloric can alone be evolved from the blood, and the absence of which (vital action) no artificial application of heat can compensate for any length of time. As the cold stage of cholera is confessedly the most important, I shall say but little upon the subject of after-treatment. Great care should, however, be taken to moderate re-action, for in all other fevers the hot stage bears a due proportion to the stage of oppression, and as in cholera that stage is severe, so we may expect violent re-action. I have not yet had sufficient opportunities of judging of Dr. Stevens's plan, but am disposed to think highly of it in the treatment of all malignant fevers.

With respect to the cholera, as it now exists in Sunderland, it appears to me to be of little consequence whether it has been imported or generated on the spot. Is it contagious, or is it not? I think no one will deny that typhus *has been* generated in England, or will say that it is incapable (under certain circumstances) of being communicated from man to man. And why may not a fever, with symptoms resembling those of cholera, also be generated in England?

In concluding this letter, I will just mention a case of cholera which occurred in this town in the early part of October. The symptoms were *completely* those of "Asiatic cholera." The patient a debilitated, tippling, old man of sixty, and death took place within thirty hours, yet there was not the least reason to suspect contagion from abroad, nor did any other individual of the family suffer from it.

It is beyond all doubt that cases do now and then occur in this country, in which it is utterly impossible (as far as

symptoms go) to say whether the disease is of Asiatic or of English origin.

I have neither time or space for any observations on fever in general, or on those more commonly met with in this part of the kingdom; I must therefore defer any thing I could wish to say on the subject till some future opportunity.

I remain, sir,

Your very obedient servant,

JOHN TWEEDALE, M.D.

Lynn, Norfolk, Nov. 28th, 1831.

DISEASES OF THE BRAIN.

To the Editor of the London Medical Gazette.

Wolverhampton, Oct 5, 1831.

SIR,

I SEND you notes of two cases of ramollissement and hypertrophy of the cerebrum, observed by me at La Pitié, in the service of M. Louis, who had never seen but one similar case; and I am not aware of any author who has mentioned such a morbid appearance. If you think them worthy of it, I shall feel honoured by their insertion in any number of the Gazette not occupied by more important matter.

CASE I.—On the third day, after a natural and easy confinement, this patient was seized with a pain in her head, but not sufficient to prevent her from getting up, and attending in some degree to her household affairs. The next day, while up and dressed, she became suddenly insensible, and the day following was brought in that state to the hospital. At the visit on the sixth day from her confinement, she was comatose, pupils contracted, mouth slightly drawn to left side, right arm and leg rather rigid, but sensible when pinched. During the visit, her breathing became stertorous. Ordered to be bled.

Next day, eyes wide open, and not fixed, but she gave no answer even by signs when questioned; breathing natural. Died during the night.

Autopsy.—The skull-cap and dura mater were adherent at the top of the left hemisphere, and the latter was torn in two places in removing the cranium. The suarachnoid tissue was full of vessels, and distended with serum. Upon

tearing away the pia mater, a good deal of the cortical part of the left hemisphere came away adhering to it. The whole of that hemisphere was softer than the right, and the corticle was red, and even purple in parts, from an appearance of venous effusion into its substance. The medullary part of that side had a grey tinge, and the red points seen upon slicing it were more numerous and darker in colour than usual. These appearances lessened as the brain was sliced lower; but, upon making a section through the corpora striata, both that and the thalamus of the left side were softer *and a third larger than those of the right side*. Indeed, a vertical section would have fallen far to the left of the usually central parts of the brain. The left side of the pons was in the same state, but the medulla oblongata and cerebellum were unaffected. The heart was rather softer than usual. This patient was rather thin, of middle height.

CASE II.—No history of this patient, a prodigiously fat woman, could be obtained: she came in, in a comatose state, with paralysis of the right side, and died in a few hours. The membranes of the brain were injected. Upon making a section of both the corpora striata, the same enlargement and softening were found as in the former case, but the medullary matter was of a yellow tinge on the left (the affected) side. The rest of the brain was healthy. In both cases, the convolutions of the affected side presented a flattened appearance.—I remain,

Your obedient servant,

T. OGIER WARD, M.B. Oxon.

NEURALGIC AFFECTION OF THE LEG,

With Chronic Thickening of the Periosteum,

CURED BY THE SULPHATE OF QUININE.

To the Editor of the London Medical Gazette.

SIR,

THE sulphate of quinine is a remedial agent so well appreciated by the profession, that there are few who have not observed, at some period of their practical career, the beneficial effects arising from its employment. That it is a most va-

luable medicine in the treatment of intermittent fevers, and of other fevers after the subsidence of the inflammatory stage, is a truth which cannot admit of doubt or controversy; but its virtues, in the cure of various other diseases incident to the human fabric, have not been so fully experienced, nor so highly lauded. However, it will be readily admitted that the celerity and permanency of relief afforded by any particular plan of treatment, furnish the most incontrovertible arguments that can be adduced to prove the rational and consistent principles upon which that plan is founded. From several cases that have fallen within my own observation, I am disposed to think that the sulphate of quinine, administered in neuralgia; will often be found an efficient method, not only of alleviating but of removing this most acute and distressing affection; and I have ventured to forward for insertion in the Gazette the accompanying case, as tending to evince its efficacy in certain chronic diseases, exhibiting somewhat of an intermittent character.

The subject of the following account may be said to have obtained a radical cure, inasmuch as she has had no recurrence of the symptoms characterizing the disease for the last six weeks.

I have the honour to remain, Sir,

Your obedient servant,

CHARLES THORNHILL.

Darlaston, Staffordshire,
Nov. 12, 1831.

Mrs. H. M. ætat. 55, of stout make, and sallow complexion, has for the space of three years suffered considerably from swelled legs, accompanied with violent and frequent pain in the muscles of the right leg, and with such extreme weakness in it as to render her incapable of performing her domestic duties. The pain has usually commenced about the neighbourhood of the heel, pursuing its course in the direction of the gastrocnemii muscles; but during the last six weeks previous to my being consulted, it had increased to such an intolerable degree as entirely to destroy her nightly repose. She states that it has been of a burning character, and that she has been obliged to keep a tub of cold water constantly in her chamber, into which she might immerse her leg to obtain temporary relief. The periods of exacerbation have been about sun-rise and sun-set; but a

distinct and well-marked interval has always been maintained between the paroxysms.

On examination, Aug. 3, 1831, (the time of this report,) a great thickening in the periosteum of both tibiæ was observed, and the veins of the leg were tortuous and varicose. The heat was much increased above the natural standard, and on making pressure along the seat of pain, extreme tenderness was manifested. In the right leg there was the cicatrix of an old wound, which had occupied the muscles of the inner calf about two years back, and which she described as having been healed with difficulty; and the heel itself seemed to be drawn up to the extent of an inch and a half, from a shortening in the tendo achillis. With respect to the constitutional symptoms it may be remarked, that the health had not undergone any material change. The pulse was rather increased in frequency, and the tongue coated with a whitish fur; the appetite was not much impaired, but the liver was deranged in its functions, as was pretty evident from the jaundiced appearance which the skin presented. In answer to several enquiries, she stated that twelve years ago, while resident in the West Indies, she had had a most violent attack of ague, since which she has been occasionally subject to a return of the symptoms resembling it. As the disease in question appeared to bear some comparison to ague, in regard to the exact approach of the paroxysms, and the remarkable interval between them, I was induced to direct my treatment accordingly.

R Pil. Hydrargyri gr. iv.

— Saponis c, gr. v. M. fiant pilulæ
ij. Omni nocte, horâ somni sumendæ.

R Quinina Sulphat. gr. ij.

Pulv. Cinnamomi c. gr. v. M. fiat pulvis, ter. die sumendus.

5th. The relief obtained has been but of trifling importance. Her appetite is a little improved, but the pain has returned as heretofore, and the legs continue at about the same temperature as at the last visit.

Cont. pilulæ.

R Quinina Sulphat. gr. iij.

Pulv. Aromat. gr. vj. M. fiat pulvis,
ut antea sumendus.

She has been directed to apply con-

stantly to her legs folds of linen-cloth, dipped in vinegar and water.

7th. Evidently better, having passed, to use her own expression, a more comfortable night's sleep than she has done for the last twelve months. The legs are not so tender on pressure, neither is there so much thickening of the periosteum; the pain still returns at the usual periods of accession, but does not remain so long as it was wont.

Cont. medicamenta.

Directed to roll the legs with flannel bandages, which are to be drawn as tightly as she can bear them.

11th. The improvement is still apparent; the return of pain is scarcely perceptible, and she can walk with comparative ease. Her countenance and skin are not so much tinged with bile as when I first saw her, and her sleep is less disturbed. The bandages have afforded wonderful relief.

Cont. pulveres, sed omitt. pilulæ.

21st. Up to this period the amendment has been gradual; last night, however, the pain returned at the accustomed time, but subsided after continuing for an hour; the bowels are rather in a constipated condition.

R Quinina Sulphat. gr. iv.

Pulv. Cinnam. c. gr. v. M. ft. pulvis ter. die sumendus.

R Pil. Rhæi Comp. ʒi. Fiant pilulæ xij. quarum duæ horâ somni pro re nata sumendæ.

Oct. 1st. Since the last report, every unpleasant symptom has disappeared, and she can walk without the aid of her stick.

MEDICAL GAZETTE.

Saturday, December 17, 1831.

“Licet omnibus, licet etiam mihi, dignitatem *Ar-tis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”—CICERO.

PROSPECTS OF A NEW ANATOMY BILL.

MR. WAREURTON is going to do something at last in the way of agitating the anatomical question: what that something is, however, we are not sufficiently fortunate to have yet discovered; but

211.—IX.

this we may venture to say, that in all conscience it is full time that something were really done. If the slowness of the process of bringing it forward is to be taken as any earnest of its perfection, this new measure must assuredly be very perfect indeed: the protracted nature of its progress would strongly remind one of what is said of the tedious, though triumphant parturition of the lioness—*diu parturit læna catulum, sed leonem*.—only that one part of the comparison unluckily still remains to be made out.

When Lord Calthorpe, on the night on which the former bill was withdrawn, was endeavouring to persuade their lordships to give it a second reading, he ventured to throw out the following prognostications:—“As to postponing the measure, he begged of their lordships to consider how the interval between this period and the *next session* of parliament would be spent. It would be an interval, not only of consideration, but of the continuance of a practice which all agreed in reprobating: it would perhaps be an interval during which *those crimes would again be committed* which had long been suspected, and which last year were brought to light. It would be continuing, and continuing unnecessarily, an odious stigma upon a liberal and enlightened profession—upon a profession which existed only for the public welfare, and whose services and whose respectability gave them a claim upon the protection of their lordships. He had no hesitation in saying that *the grievances* that might be *caused by delay* would be *infinitely greater than the benefit*.” And if his lordship has not proved himself a true prophet in saying so, never was any prediction justified by the event. We have had, however, a much longer time to test the accuracy of the prognosis in the present case than Lord Calthorpe had any idea we should. It was uttered in 1829, (June). Two complete sessions have

since gone by, and nothing in the shape of remedy has been attempted, while the evil has been advancing at a frightful rate of progress.

Yet there are those to be dealt with, it would seem, whom apparently no train of "grievances" can move. "Wait a little longer," "the time is not yet fitting," they tell us, "for entering upon this serious discussion;"—"the subject is one, the difficulty of which is equalled only by its importance; however, in the present excited state of the public mind it would be well to avoid all agitation of the subject, and it would in especial be *wise to delay* any legislative measure regarding it till that excitement has abated*." Now we would humbly presume to differ with the propounder of this advice: we make bold to question the prudence which dictates it; and we fearlessly appeal from the Lord Chancellor to *Mr. Brougham* to decide whether the urgency of the matter at issue is not more than sufficient to justify the overlooking of a mere temporary excitement. That excitement, we hold, makes for the active rather than the contemplative bearing of the friends of anatomy. Now, if ever, may the necessity of legislating for the regulation of the schools be properly appreciated—be *felt*—be set in the strongest light—be enforced. Excitement! Why, so there is an extraordinary degree of public excitement abroad; but let us understand what is supposed to be the object of it? what is the crime—who the guilty individuals that have originated this strong feeling in the public mind? Assuredly not the profession: the lowest rabble in the community are not so stupidly insane as to impute the dark atrocities of the burking system to the practitioners of physic: they are not so destitute of the least spark of reason as to be unable to draw a line of distinction

between the most unnatural of murderers and the benevolent alleviators of their infirmities. The wants of the profession are far better understood by the lowest vulgar than the interested preachers of *excitement* are willing to admit, and we are confident, that if the present opportunity of legislating be allowed to slip by, without making the requisite provision for the interests of science, government will be accountable for a most serious oversight, the public will remain exposed to the most grievous calamities, and the profession will certainly—not be the losers.

But Lord Brougham is for delay. Now what is more easily accounted for than this disposition of his lordship? At the present juncture, the state of public business is arrived at its height and most pressing urgency: along with the alarm naturally excited by the advancing ravages of a new pestilence, the necessity of deeply weighing those great political changes which are forced upon their consideration, devolves a heavy duty upon his Majesty's ministers, and upon none more imperatively than the noble lord on the woolsack. In a parliament assembled unusually early for the despatch of business of great national moment, the introduction of a *new* measure is any thing but welcome; however urgent, it is permitted to divert attention with reluctance, and the possibility of any reasonable excuse or delay is eagerly grasped at. Mr. Warburton may be very much at leisure—*degagé*, as he has been for the last two sessions, from the plague and annoyance of getting up a new bill for anatomy. The Lord Chancellor, however, is placed in quite another predicament; any new bill for regulating the schools must throw the main responsibility upon government; and we all know the extreme trust reposed in the exalted individual in question, both by his Royal master and his noble colleagues in the cabinet. To gain time then, rather

* Lord Chancellor's speech in the House of Lords (Thursday, 8th) on Lord Harrowby's motion that the petition of the Hunterian society be read.

than to eschew any prevailing excitement, may not unreasonably be conceived to be the real object of his lordship. As an individual, when he was plain Mr. Brougham, and that not above three years ago, no man could have shewn himself more sensibly impressed with the difficulties which impeded the study of anatomy, and the importance of having those difficulties removed. In that trial at Lancaster, in which Messrs. Davis and Blundell were fined and put to serious expense, for "having in their possession a body which had been disinterred for the purposes of *illegal and indecent* dissection," Mr. Brougham, who was for the defendants, displayed a thorough knowledge of the bearings of the subject, and set before the jury, in the clearest light, how "without dissection, anatomical and surgical studies could not be carried on; how professorships of anatomy had been established by the crown in our universities; how those professorships were useless without dissection; and how dissection could not be carried on without a supply of dead bodies." The climax was complete. But the law—the law—took its course; and the learned Baron (Hullock) who presided, stuck to the very letter of it:—"However necessary it might be," said his Lordship, "for the purposes of humanity and science, that *these things*" (his Lordship means dissection) "should be *done*, yet, as long as *the law* remained as it was at present, the having of bodies for dissection was an offence *liable to punishment*."

It will be a difficult matter, no doubt, to please all parties, with whatever bill Mr. Warburton may please to provide. His last had many faults, some of them of too obvious a nature to be retained; but yet the principle, we will maintain, was unexceptionable; it went to the removal of absurd and fatal inconsistencies from our statute books; and though the remedy was not as complete as the

necessity of the case required, the putting forth the hand to the cure was good, and gave more than a mere promise of success. Many symptoms of conversion too, we are happy to state, have been manifested in certain high quarters, since the last discussion of the bill in the House of Lords; and Lord Tenterden is not the only example among the lay peers, who has expressed his willingness to support a *new* measure, introduced with certain equitable conditions; while the Right Reverend Bench are said to have modified greatly their repugnance to the question. The Bishop of London will give it his decided support.

LAST night (Thursday, 15th) Mr. Warburton obtained leave to bring in his new bill. From what fell from him on the occasion, we learn that the present measure is to be *more simple* than the last; that instead of licenses being required, inspectors, appointed by the Home Secretary, are to visit the schools and make returns; and that, instead of drawing a line of distinction between the rich and the poor, "*nobody*, under the provisions of the new bill, is to be given for dissection without the consent of the person when alive, or of his nearest relative after death." We have not room for remark.

DRS. RUSSEL AND BARRY.

WE understand that Dr. Russell is to be created a baronet, and that Dr. Barry is to receive the honour of knighthood, with promotion.

LIGATURE OF THE SUBCLAVIAN ARTERY.

THIS, certainly one of the most difficult operations in surgery, was performed by Mr. Brodie last Tuesday, on a patient at St. George's Hospital. The case is one of subclavian or axillary aneurism—for the disease extends very low down the vessel—occurring in a man about fifty. The external incision was made pretty free, and great care taken, in the subsequent dissection, to interfere with the nerves as little as pos-

sible; a point to which Mr. Brodie has been led to attach considerable importance. Considerable dexterity was required in detaching the vessel from the surrounding parts, as the artery was enlarged, and there was a good deal of thickening in its vicinity. The end in view, however, was fully accomplished, and we need scarcely say with the utmost skill. We shall give the details when the result is known.

DISSECTION OF BISHOP.—PHENOMENA ATTENDING DEATH BY STRANGULATION.

On the occasion of examining the body of Bishop, at King's College, Dr. Watson, the Professor of Forensic Medicine, stated, that he had been requested by his colleagues to make some observations on the phenomena presented by certain modes of death, but more particularly by suffocation. Although he could not hesitate in complying with their request, yet, being thus suddenly called upon, he must bespeak their indulgence for appearing before them for the first time in a manner so unprepared.

Dr. Watson then alluded to the infrequency of opportunities of examining cases of strangulation in the human subject, with an accurate knowledge of the precise mode and time at which death had taken place; and remarked, that the information obtained under such circumstances was often of much use in throwing light upon other cases, of a doubtful nature; with regard to which, medical men were frequently called upon to give evidence. He then proceeded to speak of death by *suffocation*—a term which, used generally, he preferred to asphyxia, as this last meant literally absence of pulse, and therefore was most applicable to death beginning at the heart. Suffocation, it might be observed, presented several varieties; such as that produced by suspension, by submersion, and by the inhalation of gases destitute of oxygen. He remarked that the older physiologists entertained erroneous ideas as to the cause of death when the supply of air was cut off. Haller, for instance, conceived that the blood, under such circumstances, was no longer able to pass through the lungs, and that the circu-

lation in these organs was arrested by the mechanical condition of their vessels. Goodwyn made a step towards the truth, by shewing that the blood continued to pass through these organs; but he imagined that, arriving at the left side of the heart, destitute of its usual stimulating properties, this refused to contract upon it, and thus ceased to transmit it to the brain and other parts; death then resulted from syncope, the brain and heart being simultaneously affected. It was reserved for Bichat to demonstrate the exact mode of death in such cases. He, by very simple but convincing experiments (which Dr. Watson briefly detailed), was able to prove that the blood continued to be propelled by the heart, though it had lost its arterial properties. Thus coming into contact with the brain, it was first destructive of the functions of animal life; and being circulated also over the whole body, including the structure of the heart itself, it acted as a poison on the various parts, till at length the organic life yielded to its pernicious influence; death, in fact, ensuing from the circulation of venous blood in all parts of the body, which produced its effects by killing first the brain and nervous system, and subsequently the heart and muscular system; the insensibility beginning as soon as the dark blood arrived at the brain, but the heart continuing the circulation some time longer.

Dr. Watson next proceeded to inquire what evidence was to be derived from the appearance of the body, as to whether an individual had been destroyed by suffocation. Various criteria had been mentioned by different authors, but these were, for the most part, very uncertain and inconclusive. Among these were, the body remaining long warm and pliant; partial contractions, as of the hands or feet; the appearance of spots upon the surface, &c.; even the appearances about the face of lividity and tumefaction, with projection of the eyes, though of more importance, were nevertheless not to be depended upon, inasmuch as they are occasionally absent. Upon the whole, the most important phenomenon was the congested state of the venous system generally, but more particularly of the lungs, of the left cavities of the heart, and of the brain. A circumstance, however, which prevented such appearances from

being conclusive of suffocation, was, that they were met with in cases of death beginning at the head, as in coma; in which cases also the circulation of black blood took place, but which was then to be regarded as the effect, not the cause, of the cessation of animal life. The appearances of congestion, however, were not to be taken as conclusive, because it had been shewn by Bichat that they were generally absent in those in whom the suffocation had been rapidly effected; as he had ascertained in examining the bodies of some persons who had been suffocated by the fumes of a furnace, and of two who had been hanged. He also established the same principle by experiments, in which he found that venous congestion did not shew itself when animals were suddenly suffocated, while it was met with in others in whom asphyxia was slowly produced, as by confining them in a limited portion of air, which gradually became deteriorated, till it was no longer capable of supporting life.

Morgagni was aware of these facts, and has offered what appears a satisfactory explanation of them. He states, that the blood in those suddenly cut off, does not coagulate, but, remaining fluid, becomes distributed after death, although congestion in the venous system *has been* present. Thus he opened the chest of a person who had been hanged, about two hours after his death, and found the lungs and right cavities of the heart gorged with blood; the right auricle, in particular, was prodigiously distended, and seemed ready to burst; but on looking at the body next day, these appearances were entirely gone: the vessels not having been opened, and the blood which remained fluid having found its way by various channels, had left the heart comparatively empty and flaccid.

Dr. Watson then remarked that considerable difference of opinion had existed as to the exact mode in which death was produced by hanging. Some held, and he believed correctly, that it depended upon the circulation of black blood through all parts of the system; others, again, regarded it as the effect of apoplexy, produced by the pressure of the rope on the veins of the neck; and yet others sought for the cause of death in the fracture of the spine, and consequent injury to the spinal cord, which sometimes took place. He

stated it to be his opinion, however, that though one or both of the latter circumstances might concur with the circulation of venous blood, and might even be conceived sometimes to anticipate the slower death from this, yet that generally they were to be looked upon only as secondary and accidental causes. In corroboration of this opinion, he mentioned the experiment which had been made by Mr. Brodie, amongst others, in which a dog had been suspended for a considerable time, but an aperture having been made in the trachea, lower down than the rope, the animal continued to live. The external pressure doubtless has a tendency to produce insensibility, as is shewn by compressing the neck by way of experiment: besides which, he adduced the case of a patient, brought to Middlesex hospital, who had attempted to hang himself: he was cut down while yet alive, but continued insensible, though several hours elapsed before death took place. He also referred to a case which occurred some years ago in Edinburgh, where a felon had been cut down by the rabble, and remained nearly an hour in a state of insensibility, but still living, until the execution was completed by the proper authorities.

Dr. Watson was anxious to press upon his hearers that, as shewn by Bichat, an interval occurred between the cessation of animal life and of the organic functions, so that the heart continued to act after sensibility had ceased, and that this interval was of great importance, inasmuch as, by artificial respiration, individuals might possibly at this period be restored. From the rapidity with which consciousness was destroyed, it was evident that suffocation was one of the easiest modes of death, and it was probable that hanging was particularly so; as the external pressure co-operated with the other circumstances in producing insensibility. There was reason to believe that the sufferings of the individual were entirely at an end as soon as black blood reached the brain (a period generally marked by the occurrence of convulsions), although life was not yet extinct, as the circulation continued for some time longer. The idea of the comparative easiness of this mode of death was in conformity with the account of their feelings given by all those who had been restored after suffocation. Many such cases are on

record, all very much resembling each other. Morgagni, for instance, states that a person who had thus been resuscitated told him, that he had felt no pain, but that he had perceived flashes of light before his eyes, and speedily passed into insensibility. When Dr. Watson was at Edinburgh, a man was brought into the Infirmary who had attempted to hang himself. His account was, that he had seen a dazzling brightness before his eyes—that the windows of the room appeared larger and more numerous than natural; after which he “forgot himself.” Lord Bacon, in his *Historia Vitæ et Mortis*, gives an account of a friend of his, who, being desirous of ascertaining what were the sensations of those who were hanged, suspended himself, thinking he should be able to regain at pleasure a stool on which he had been standing; but he soon became insensible, and would have died had not some one come to his assistance; and Dr. Watson remarked, that probably most of his hearers might be able to call to mind instances where this sort of experiment had come to a fatal termination—analogous accidents being from time to time recorded in the newspapers. As Lord Bacon’s account was quaint and short, while it afforded a fair sample of such cases, he quoted his words:—

“*Memini me accepisse de Generoso quodam qui lubricundus ex curiositate desiderabat scire qualia paterentur in patibulo suspensi; sesèque suspendit, super scabellum se alleuans, et deinde se demittens; putans etiam penes se futurum, ut scabellum pro arbitrio suo, recuperaret id quod facere non potuit; sed tamen ab amico præsentè adjutus est; ille interrogatus quid passus esset? retulit se dolorem non sensisse; sed primo obseruansatam sibi fuisse circa oculos speciem ignis et incendii; deinde extremæ nigredinis sive tenebrarum; postremo coloris ejusdam cærulei pallidioris sive thalassini; qualis etiam conspicietur sæpè animo linquentibus.*”

The Professor next spoke of the special marks to be expected on the body after hanging. 1st. A depression corresponding to the size and position of the rope, generally with ecchymosis extending more or less into the subjacent parts. Where this mark was strictly horizontal, it afforded proof that the strangulation had not been produced by *hanging*.

Fracture of the spine Dr. Watson stated to be less common than was generally imagined, and its presence had been thought to shew that the individual could not have committed suicide; but if the person had thrown himself from any height, especially with a long rope, it was quite evident that the occurrence in question might take place. He next adverted to the appearance of the face, which was generally purple or livid and swollen, with the eyes blood-shot and staring. Sometimes the tongue protruded, but this would depend upon the spot at which the rope was applied, for if it encircled the neck high up, *as in the case before them*, it necessarily pulled the os hyoides and parts attached to it backwards. Shakspeare has well described the ordinary appearances under such circumstances:—

But, see; his face is black and full of blood,
His eye-balls farther out than when he lived,
Staring full ghastly—like a strangled man.

He pointed out, however, as necessary to be kept in mind, that these appearances of turgescence and lividity of the lips and countenance, even when present at first, were likely to disappear when the blood remained fluid, particularly if the head had been in an elevated position. Dr. Watson also alluded to the occasional erection of the penis, described as occurring in such cases. With regard to the internal appearances, they were principally those of venous congestion, in the head, chest, and abdomen. Dr. Watson particularly mentioned the cases related by Dr. Yelloly, wherein he had found in the stomachs of five criminals, who had been hanged, great congestion in all, while in two, there was blood extravasated and coagulated upon the membrane itself. These cases he thought extremely important, as shewing the danger of mistaking such appearances for inflammation produced either by poison or otherwise.

Mr. Mayo then proceeded to examine the body.

The integuments of the face and head loaded with blood; some tumefaction and lividity of face, but not so much as there had been just after the execution; tongue not protruded; mark of the rope just under the chin. Part exposed by dividing the scalp excessively gorged with blood; some appearance of ecchymosis. On removing the skull-cap, little appearance of congestion; slight serous effusion beneath the arachnoid;

numerous bloody points on slicing the brain; a little water in the ventricles; surface of cerebellum gorged; perhaps a little extravasation. Lungs and investing membrane perfectly healthy; back part of these organs loaded with blood, but not more than large; cavities flaccid; blood perfectly fluid, running into large vessels when the heart was raised, and back again on letting it fall. No particular congestion about the stomach. Colon much-distended with flatus. Other appearances natural.

—

TRANSFUSION OF BLOOD TRIED IN CHOLERA—ITS FAILURE.

At a late meeting of the Academy of Science, in Paris, M. Arago read a letter from Professor Scoutetten, of Metz, on the transfusion of blood in cholera. We extract the following passages:—

I have the honour of addressing to you some observations, which I have made at Berlin, on the transfusion of blood: the facts speak for themselves: be good enough to read them at the next meeting of the Institute; they may be useful to science and humanity, and perhaps prevent some unfortunate patient from being the victim of new experiments. The complete absence of blood in the arteries of the limbs appears to me a very remarkable fact, and the more astonishing that some lived in this state during five or six days, the capillary circulation being restored, with the heat of the limbs, without the pulse being perceptible. I have numerous facts of this kind, particularly the history of a Pole, who was able to walk about without the pulse having returned. He died suddenly, when it was least expected; and this was the result in all those cases of which I speak.

CASE I.—After having tried all the ordinary means in a case of cholera, it was thought right to have recourse to transfusion of blood. October 15th the operation was tried for the first time, by M. Dreffebach, in the hospital of M. Boehr. The patient, Frederick Muller, of good constitution, aged 27, had been ill seven hours and a quarter, and he was in the following state. Eyes half shut, sunk in the sockets, ball turned upwards; nostrils pinched; cheeks hollow; mouth par-

tially open; tongue cold, as well as the face; respiration short and quick; blueness of hands and feet; complete absence of pulse; skin of fingers shrivelled. The patient, however, retained perfect consciousness of what was passing around him. The right jugular vein was laid bare to the extent of an inch, and opened in a longitudinal direction, and the barrel of a quill introduced into it. Blood was furnished from the median vein of a robust young medical man. It was received into a small brass syringe previously warmed, and injected into the vein of the patient to the extent of an inch and a half. This was followed by almost complete insensibility; after which the patient made two deep inspirations in succession; the eyelids were rapidly opened, and again shut; in five minutes there were convulsive movements of the head, which was drawn powerfully backwards; next followed convulsions of the legs, arms, and trunk, alteration of the features, plaintive cries, and groans. These symptoms lasted less than a minute, then ceased all at once, and the patient was dead. It is said that no appearances different from usual were found on opening the body.

CASE II.—The same day, transfusion was tried on a female, named Veber, aged 65. She was taken ill during the night; the operation was had recourse to at ten o'clock next day. The following is an account of her condition. Eyes sunk, and surrounded by a brownish circle; cheeks hollow; bones of face prominent; tongue hard, and feels cold; complete absence of the pulse; vomiting and purging rare; consciousness entire. The only remedy used had been a vapour-bath.

M. Dreffebach proceeded to the transfusion. The median vein of the left arm was opened to the extent of half an inch: very little blood flowed from it. A quill was inserted, and blood furnished by a student 23 years of age. The first injection, of an ounce of blood, produced no effect; the same quantity was thrown in a second time. The patient then made two rather hurried inspirations; the eyes were somewhat agitated. She had some mint-tea, and drank it easily. I asked her if she suffered, and she answered, "No." The operator wishing to introduce more blood, opened the left jugular vein, into which he injected about a drachm

of tepid water, to be assured that there was no obstacle. He then threw in, at two injections, two ounces and seven drachms of blood. The patient felt nothing. The day was passed tranquilly; the pulse did not return. The usual symptoms went on, and she died six hours after the operation.

CASE III.—A man, aged 61, seized with cholera, was admitted into the hospital on the 16th of October. All the symptoms were well marked. The attack had come on about midnight. At ten o'clock in the morning the operation of transfusion was decided on, but, before putting it in practice, it was resolved to ascertain whether the circulation did or did not go on; with which view M. Dreffebach laid bare the brachial artery, to the extent of an inch, at the lower part of the arm. The vessel did not exhibit the slightest pulsation. An opening, five lines long, was then made in it, when it was found not to contain one drop of blood: having within only a small red clot, not larger than a sewing-thread. The parietes of the artery were clean and white. The patient, meantime, was perfectly sensible, spoke of the operation, and answered with precision all the questions put to him. The deep-seated textures were as cold as the surface; the veins of the fore-arm were filled with black blood; the median was opened, and two ounces and a half of blood were injected at three times. The patient felt nothing; complained of no pain, except very slightly of the wound made to expose the artery. After the third injection the pulse returned in the axillary artery of the fore-arm; it beat sixty times in the minute, but this only lasted five minutes. Even then, not a drop of blood escaped by the wounded artery. Some appearance of contraction of the iris, it was thought, was to be perceived during the transfusion, and the expression was a little more animated. The patient died two hours after the operation, which seemed to have had no influence on the course of the disease.

for Wednesday the 14th, to take into consideration the petition to be addressed to parliament on the subject of anatomy.

After which the question of the nature of malignant cholera, particularly with reference to its identity with the disease in England, was taken up by

MR. SEARLE, who read the following paper. Having stated it to be his opinion, that "cholera spasmodica and cholera morbus were intrinsically the same, but not identically so," he held the cause of the former to be a poison of the sedative class, operating immediately on the brain and nervous system. Its *modus operandi* he illustrated in the following manner, having premised that the action of the capillary vessels was independent of the heart and brain, the only essential stimulus to their function being the presence of duly arterialized blood. The poison causing cholera, he regarded as a miasm similar to, if not identical with malaria, and this he conceived to be received into the lungs by the act of respiration, and thence to contaminate the blood; its effects being particularly directed to the general capillaries of the system, destroying their functions—viz. nutrition, secretion, calorification. From this follows primarily, the languor, indigestion, giddiness, &c. and secondarily the purging, vomiting, coldness, spasms, &c. From the progressive depreciation of the functions implicating the respiratory process, the blood becomes surcharged with carbon, from which the evil becomes extended, causing the lividity of surface; and the numbness, pain, and cramps, are produced by distention of the veins of the spinal marrow at the origin of the nerves. Such is a general outline of the extended detail into which Mr. Searle entered in explanation of the cause of Indian cholera, and its mode of operation. He had no doubt but that sporadic cases of the disease often occurred in this country, and this led him, in the second place, to inquire in what the above disease differed from ordinary European cholera? "They differ little (said Mr. Searle) but in intensity of disease, as dependent upon the difference and virulence of the cause which gives rise to it, as we see illustrated in the operation of various other poisons of the sedative class upon the system;" and "it is to this difference of cause, or character of the poison giving rise to these analogous affections, to which I am of opinion the specific difference in the character of the disease may be fairly attributed." The poison producing the Indian cholera, Mr. Searle stated, as above, was applied from without; the cause of ordinary cholera, he believed to be "a poison generated within;" or that it resulted from the blood's "imperfect decarburation." This, again, being the result of the biliary derangements resulting from heat, cold also, by causing "cuticular capil-

WESTMINSTER MEDICAL SOCIETY,

Saturday, Dec. 10, 1831.

DR. STEWART IN THE CHAIR.

AFTER some discussion, it was agreed that a special general meeting should be called,

lary torpor," was pointed out among the agents capable to produce cholera morbus; and this cause co-operating with exposure to malaria, was stated to be productive of an aggravated form of disease; in illustration of which he read an extract from his pamphlet, beginning at page 34.

In concluding (said Mr. Searle) this part of the subject, sir, I think I have made it appear that the cause of cholera, whether spasmodic or otherwise, is that of a sedative poisonous agency upon the system, in support of which opinion, and that malaria is the cause of the former species, or very frequently so, I would adduce the fact that at Berlin the post-mortem appearances of the choleric invariably exhibited an affection of the mucous membrane of the bowels, which I have since found, on reference to the London Fever Hospital, almost invariably to attend upon fevers which are generally acknowledged to originate in malaria. And I would adduce also the cases of the disease occurring at a school at Clapham, which were so much alike in character with the spasmodic cholera, and which there was demonstrative evidence were dependent upon a cause of the same kind; and that it is to the presence of accumulated carbon, resulting from the blood's defective oxygenation during the summer months, acting upon the system as a poison, that cholera morbus is to be attributed, may, I am of opinion, fairly be inferred, by the fact of other poisonous agents, of the same character, producing analogous effects upon the system; as I have frequently witnessed in India, in persons who have partaken of oysters, which it may be supposed were not perfectly fresh; and the same thing Dr. Prout mentioned to me he had witnessed in all the members of a family who had eaten of a turkey which it was supposed could not have been fresh; and I have the authority of Sir Astley Cooper for saying that the effluvium of the dissecting room, when he has had a putrid subject, invariably produces the same effect with him. The opinions, sir, I have now had the honour to communicate to this Society, although not hastily formed, have been hastily committed to paper; which I hope will plead my apologies for their being not quite so perspicuously worded as I could have desired.

After the conclusion of Mr. Searle's paper, a very long pause ensued. At length

Dr. MACLEOD rose and said, that he offered himself to the notice of the society with great reluctance; but, as the pause was becoming quite formidable, he would offer a few remarks on the paper, rather than suffer the silence to be protracted still longer. He was afraid that he had not clearly understood Mr. Searle, as that gentleman had begun by holding, that the Indian and English cholera were "intrinsically the same," while

he had afterwards gone on to prove that they were "specifically different," and this appeared to him to be a contradiction in terms. That there was great resemblance between certain cases of the Indian disease and that which occurred in England, was quite evident; had it not been so, the same name would never have been applied to both. Yet, admitting this, he still thought, that, viewing the two diseases, each as a whole, sufficient discrepancy might be observed to show, that they were not the same. Thus, in English cholera, vomiting and purging, with cramps, formed the assemblage of symptoms characterizing the more severe cases; in Indian cholera, not only might all these be absent, but their absence actually marked the most severe form of the disease. In the English disease, as a general rule, bile presented itself in the evacuations; in the Indian cholera, the absence of bile was one of the peculiarities of the disease. In the former, the secretions of the liver and alimentary canal were increased; in the latter, they were arrested, the matters passed being merely certain constituents of the blood, apparently suffered to exude from the vessels without undergoing the changes we recognize in secretions. Still it was held by some that these differences depended upon different degrees of severity; but he doubted the accuracy of this, because he had seen patients die of English cholera—which, he supposed, was as strong a proof of its severity as any gentleman could desire—yet, in these cases the individuals did not die as they are said to do in the Indian disease; they became weaker and weaker, under the continuance of the vomiting and purging, and at length sunk exhausted, as one might be supposed to do from hypercatharsis, or any other immoderate depletion; but they did not exhibit any shrivelled appearance, they did not become blue, nor shew any signs of defective arterialization of the blood, which appeared to be one of the great characters of the Indian disease. He was aware that others had met with cases in which some degree of this blueness was to be seen, and he admitted that it was the occurrence of these sporadic cases, so closely resembling the malignant disease, which constituted the greatest difficulty in deciding this question. But even admitting the great resemblance in extreme cases, still it remained to inquire, whether similarity of symptoms marked identity of disease. Mr. Searle had taken his illustration from the effect of narcotics; but adopting his own instance of opium and belladonna, he (Dr. M.) contended, that though there were certain points of resemblance, as to their effects on the nervous system, yet these by no means went so far as to constitute their actions "intrinsically the same." Besides, a man might be found in the street in a state of stupor,

and it might be impossible to say from his appearance whether he had fallen down in apoplexy or had received a blow on the head, or was only very particularly drunk; yet no one looked upon a fit of apoplexy, a blow on the head, and intoxication, as "intrinsically the same." Again, a female might have convulsive paroxysms, of which no one, regarding the present appearances merely, might be able to say whether they were epileptic or hysterical; while it was farther notorious, that tetanus and hydrophobia frequently resembled each other so closely as to have been actually confounded; and this last instance bore directly on the point at issue, because the former, like English cholera, was produced from accidental causes; the latter, like the malignant disease, arose from a peculiar poison. The speaker inferred from all this, that similarity in certain symptoms was not sufficient to show individuality of disease. But if they who founded the doctrine of the identity of English with malignant cholera on their resemblance, did not on this point prove enough, there was another on which they proved too much, for some of them also held the new cholera to be the cold stage of a malignant fever. Now he was far from objecting to this doctrine; but as it was an admitted axiom, that "things which are equal to the same, are equal to one another," so, if English cholera be equal to Indian cholera, and if malignant fever be equal to Indian cholera, English cholera must be equal to malignant fever! He by no means objected to the comparison of the new disease to fever, because he thought it the more correct view; but by how much the more any one succeeded in establishing this doctrine, by so much the more did he disprove the former part of the proposition, because any one who had seen common English cholera must perceive that the attempt to prove it to be the same as malignant fever, was an *argumentum ad absurdum*.

Dr. JAMES JOHNSON objected to the presence or absence of bile as forming any diagnostic mark of English cholera; bile was not generally present in the disease of this country, at least it was not so at the commencement, but was produced by the succussions of the vomiting. He held that the vomiting of bile in the cholera morbus was only a ternary link in the chain of phenomena. The contents of the stomach were first discharged, then the mucous secretions of that organ, and lastly bile. He remarked farther, that there was something superadded to the causes of common cholera, which rendered that disease epidemic; but what that something was he (Dr. J.) did not pretend to know.

Dr. GREGORY rose to animadvert upon two points touched upon by the preceding speaker. Dr. J. Johnson had then reiterated a sentiment on which he seemed to lay

great stress—the absence of bile in the first discharges from the stomach in cholera morbus. It was Dr. Johnson's object to shew, that the vomiting of bile, when it *did* occur, was merely the result of the continued vomiting, and that bile *never* appeared in the first discharges from the stomach. This position Dr. G. would by no means consent to admit. In common with many other members of the society, he had seen numerous instances of the ordinary cholera of this country, and he was perfectly satisfied that bile was often seen in the very first discharges from the stomach. He was ready to concede to Dr. J. that these first discharges consisted of the *contents of the stomach*; so did the second; so did the third and the fourth; but the question was, whether bile is not often in the stomach *prior* to the first attack of vomiting? Dr. G. was firmly convinced that it was; and that nausea and headache are often evidences of such an occurrence. How often do we find persons bringing off bile—pure bile, from the stomach, by a single effort of vomiting; and if this can happen independent of cholera, why may it not happen in that disease? [Dr. J. Johnson here expressed some dissent.] Dr. Gregory added, that he spoke not of *possibilities*, but of every-day occurrences, and he left it to the members of the society to judge between them. Dr. G. then proceeded to comment on that part of Dr. Johnson's address which referred to the obscurity in which the causes of epidemic cholera was involved. To this sentiment *in itself* Dr. G. had nothing to object. Whatever notions he himself entertained on the origin of this disease, he was quite ready to admit the *obscurity* in which the subject was involved; but he was astonished that Dr. Johnson should thus profess his ignorance of that *something* which rendered the cholera epidemic, when, in the first of those nineteen propositions with which he had favoured the society, the whole matter was explained. Dr. J. Johnson's words in proposition 1st, are—"In epidemic cholera, a poisonous, or sedative principle, originating in the earth, or emanating from animal or vegetable substances, strikes a predisposed individual, and produces the disease." On numerous occasions Dr. Johnson had advocated the *terrestrial* origin of cholera; and he (Dr. G. G.) could not understand with what consistency he now maintained that the causes of epidemic cholera were beyond his knowledge. He had appealed to the new volcano in the Mediterranean in proof of the reality of such terrestrial changes as were adequate to the explanation of the origin of cholera. This theory he (Dr. G.) discredited altogether; he could not see any plausibility in the supposed connexion of cholera with terrestrial emanations; and if it depended upon subterranean heat, it would be incumbent on Dr. Johnson to prove the springing

up of a new volcano every year since 1817. Be this, however, as it might, we either did know the sources of cholera, or we did not. The observations which had just fallen from Dr. Johnson, when compared with his written statement, left it in doubt in which horn of the dilemma he desired to be placed. Dr. G. next proceeded to offer some remarks on the proposal of Dr. O'Shaughnessy, to inject oxygenating salts into the blood, as a remedy in the Asiatic cholera; but upon learning that that gentleman had gone to Sunderland for the purpose of prosecuting his researches, he desisted.

DR. GRANVILLE begged to put a question, through the Chairman, to Dr. Barry, whom he saw in the room—namely, “Whether the common autumnal, or English cholera, and the disease which he had seen in Russia, were identical?” Thus called upon, and amid the manifestation of much anxiety on the part of the meeting to hear his opinions,

DR. BARRY rose, and after acknowledging the compliment paid him, proceeded to state, in the strongest terms, his conviction that the diseases were different. He remarked that the essential characters of English cholera were often entirely absent in the other—in which patients frequently died in a few hours, and without having vomited or been purged at all; but that they were in a manner stricken down at once, and exhibited more the appearances of a corpse than a living being; with the eyes sunk into the sockets, the skin dark as if from nitrate of silver, the toes and fingers shrivelled, and the tendons standing out like rigid cords along the limbs; while the very breath was cold, and the pulse scarcely to be felt, or not to be felt at all; and this led him to observe, that the disease he had seen in Russia, and more lately in Sunderland, bore much more analogy to the cold stage of a malignant fever than to ordinary cholera; and, indeed, it was thus further different from it, that, to be successful, you had to save your patient twice—first from the blue or collapsed stage, and then from the typhus fever which succeeds. He strongly expressed his conviction that neither Celsus nor Sydenham had ever seen the disease which had lately attracted such fearful interest, because, if they had done so, it was not to be conceived that they would have omitted to mention the blue colour—the corrugation and shrivelling of the extremities—the coldness of the tongue and breath, or the alteration of the voice; yet not one of these things had either of them enumerated. Dr. Barry then proceeded to speak of the anatomical characters, the most constant of which, he said, were distention of the gall-bladder, with a most peculiar shrinking and emptiness of the urinary bladder, which more resembled a dried fig than any thing else, and was scarcely larger. He also particularly dwelt upon the phlogosed state of the spinal marrow, and its investing mem-

branes, to which, in some cases, was super-added distinct ramollissement. The observation of this circumstance had led Dr. Lange, of Cronstadt, to try the use of the actual cautery to the spine, opposite the part where the inflamed or softened appearances presented themselves. This was done in fourteen cases, twelve of which recovered; and this too at the commencement of the epidemic, the very time at which experience had shewn it was violent and intractable. In several of these cases the patients were so much satisfied of the relief afforded, that they begged for the repetition of the operation; but such were the prejudices of the people against the medical men—such their persuasion that the disease was produced by poison, and that this method was a kind of torture by burning, that it was found necessary to discontinue it. Vomiting and purging, he asserted, were by no means the cause of death in the Russian disease; the paralysis of the heart—the thickening and stasis of the blood—the embarrassed and altered respiration—were the fatal alterations of function which hurried on the fatal event, and in many cases with such dreadful rapidity.

DR. COPLAND called the attention of the society to the circumstance of his having, some years ago, as well as recently, advocated doctrines similar to those so ably supported by Dr. Barry.

A gentleman, whose name we did not learn, spoke in favour of the identity of English with Indian cholera.

MR. SEARLE made some observations in farther elucidation of his views. We understood him to say, that he regarded the disease as modified by climate, being intrinsically but not identically the same. With regard to the appearances of the spinal marrow, alluded to by Dr. Barry, he had often seen the vessels of the meninges of the brain very much loaded, and with serosity between the membranes; these appearances often extended down into the spinal canal; but nothing like softening was to be found in recent cases; and he regarded the affection as much too general to be cured by the local application of the cautery, as recommended by Dr. Barry.

—
The proposed meeting took place on Wednesday, and was adjourned without any decision having been come to regarding the anatomical petition.

NOTE FROM MR. KING.

To the Editor of the London Medical Gazette.
SIR,

IN your report of the debate at the last meeting of the Westminster Medical Society, there is an important omission with respect to the treatment adopted in the case of cholera which I related; and there is also a charge of “vociferating” brought against me.

Have the goodness to supply the former, and be assured I am not conscious of having deserved the latter. I said, that the serious symptoms in the case alluded to were checked, not merely by the application of a large mustard poultice to the abdomen, but by this means, combined with the administration of very small doses of the Tinct. Opii.

I remain,

Your very obedient servant,

THOMAS KING.

10, Hanover-Street, Hanover-Square,
December 13, 1831.

MEDICO-CHIRURGICAL SOCIETY.

Tuesday, Dec. 13, 1831.

MR. LAWRENCE IN THE CHAIR.

Fracture of the Spine—Tumors.

A PAPER by Mr. Barlow, giving an account of a case of fracture of the spine, was read. The principal feature in it was in the treatment, and that was by, in the first instance, restoring the fractured and projecting parts of the vertebrae to their proper position, by means of extending the upper and lower extremities at the same time—which gave no pain, but rather great relief; and, with the aid of mechanical contrivances for supporting and moving the body, enabled the patient to sustain life, under circumstances of considerable promise and amelioration, for upwards of twelve months. His urine he was able to evacuate by pressure on the hypogastric region. The body was carefully examined after death, and much softening of the medulla spinalis was clearly observable opposite the fracture. Drawings and preparations of the bones were exhibited to the society by Mr. Langstaff, who had communicated the paper.

MR. STANLEY considered the treatment in this case rather unjustifiable; he did not see, notwithstanding the favourable circumstances which ensued, that the method of forcibly extending the extremities was consistent with the principles of judicious management. He was surprised too at the little attention which seemed to have been bestowed on, or required by, the urinary apparatus. In a case of a similar nature which had occurred to his observation in St. Bartholomew's, a material cause of death was disease of the bladder: an ammoniacal state of the urine very early discovered itself, and in spite of all the care that could be given it, by the introduction of the catheter two and often three times a day for the last three weeks, symptoms of inflammation of the bladder supervened, and, upon examination after death, considerable sloughing was observed.

MR. LANGSTAFF presented and gave explanations of various dry and wet specimens of anchyloses, and diseased growths of bone.

He submitted to the society the proposition—that no ankylosis is ever effected in a scrofulous state of the bones; at least he, with very extensive opportunities of observation, had never found it to be the case; and he wished any gentleman present, that knew an instance to the contrary, to be so good as to come forward and state it.

Nobody gainsaying the proposition, the second part of a paper by Mr. Lawrence, on tumors, was read by the Secretary.

The relation between the tumors of which this part of the paper treated, and the pancreatic sarcoma of Mr. Abernethy, was pointed out. The tumors in question were situated for the most part about the localities of the submaxillary structures, and generally close to the mastoid process; and it might be observed of them, that they seemed invariably to partake of the nature of the tissues in the neighbourhood of which they were situated; those, for example, in the vicinity of the salivary glands bearing an analogy in their structure to those glands. A small quantity of bony deposition was also sometimes detected in them. The knife was the most speedy and effectual remedy in these cases. The paper then went on to give an account of five or six examples of the occurrence of these tumors; one in a young man, in whom the new growth attained the size of a walnut, in the angle of the jaw, close by the mastoid process, and involving the parotid gland. In the operation for its removal much hæmorrhage ensued, and a portion of the facial nerve was unavoidably cut away; the cure, however, was complete. A tumor of a similar description, and similarly situated, but of the size of a hen's egg, was removed from a woman, by a single incision. Another growth of the same character, but formidably larger, gave Mr. Lawrence much more trouble. He was obliged to cut through it in the removal; and it was seen that a considerable cavity existed in the centre, containing a fluid which seemed yellowish, but the exact composition of which could not be ascertained, owing to its mixing with the blood which flowed copiously at the time. After cutting out the remainder of the tumor, Mr. L. found it necessary to get rid of a quantity of blackish tissue which composed the nidus of the tumor, about the parotid, by breaking it down; the external carotid was completely bared in this operation. All the cases related by Mr. Lawrence were attended with successful results; the last of them was one in which a young lady, who had an ugly tumor, the size of a walnut, on her upper lip, near the angle of the mouth, submitted it to the knife; and it was readily removed from the inside, leaving the patient completely well in a day or two. The tumors in question, it was further observed, were all situated on the left side of the jaw, and none of them were of a malignant character.

DR. GORDON inquired whether any medical treatment had been tried in these cases previously to the use of the knife being adopted; and he wished particularly to know, whether iodine had been resorted to. He related the case of a woman who had a tumor removed, by an operation, from her breast, at one of the dispensaries, and upon returning some time after to the same establishment with another tumor of the same sort in the other breast, and declining to permit its removal by the knife, was induced to apply in another quarter, where the disease was treated with iodine, and with the most successful consequences. The whole tumor was not yet removed, but it was most remarkably reduced.

MR. LAWRENCE said that his cases were managed at a time when the use of iodine was scarcely known; but that various remedies had certainly been employed, such as leeches and constitutional treatment, though without any promise of success.

MR. LANGSTAFF did not think that iodine could have the least good effect in tumors, such as those described by Mr. Lawrence, any more than in growths of the nature of fungus hæmatodes.

MR. STANLEY thought that iodine was only efficacious in overgrown structures and enlargements of glands, as in bronchocoele. Before sitting down, he wished to call Mr. Lawrence's attention to a case of diseased mamma, on which an operation had recently been performed at St. Bartholomew's, for the removal of a tumor which he thought of a malignant kind. But what he wished particularly to notice, was the rapidity with which the wound, twelve inches in length, healed up—almost completely by the first intention; at least, there was not above a spoonful of matter discharged: upon this he begged to have the President's opinion, whether it was not a bad symptom, indicating the return of the disease in the part?—his own experience would induce him to conclude that it was; and he would further be glad to know, whether an issue in the neighbourhood of the part might not have a good effect in obviating a recurrence of a similar diseased growth?

MR. LAWRENCE did not think the tumor in question one of a malignant sort. As to the rapid healing of the wound, he thought it entirely owing to the constitutional healthiness of the woman, and not to any connexion with the supposed latent morbid structure. The issue he thought very advisable if a recurrence of the disorder was anticipated.

Some conversation ensued on the question—whether there really was any deficiency of bony matter in scrofulous patients; and whether, as was stated by some German surgeons, iodine was likely to conduce, in those cases, to the formation of osseous deposits? Adjourned.

DR. STEVENS IN ANSWER TO DR. JOHNSON.

—

[TOGETHER with the following letter, some documents were sent for our perusal, which appear to us fully to bear out Dr. Stevens in his statements:—1st, That the plan of giving neutral salts, in a manner not previously practised, was adopted at Trinidad on his suggestion; and 2dly, that a great diminution in the rate of mortality followed thereupon. There may be difference of opinion as to how far the success depended upon the above, and how far upon other means; but the evidence must be very different from that contained in Mr. Greatrix's letter (the original of which we have seen), to warrant the imputations which Dr. Johnson states his correspondent to have thrown upon the honour and veracity of Dr. Stevens.]

To the Editor of the London Medical Gazette.

SIR,

I HAVE had reason to believe that, for some time past, reports similar to the accusations contained against me in Dr. Johnson's late letter, have been circulating in some of the private medical circles in this city, but in so cautious a manner that they were not tangible, for I found it impossible to trace them to their real source. With a belief that such a cause was in operation against me, I was not sorry when I saw the same accusations openly and boldly stated in a public journal. Unfounded attacks, like venomous reptiles, are only dangerous when they crawl in the dark; when they venture to shew themselves in open day, the one, like the other, can easily be crushed.

At the time that my paper was written for the Royal College of Physicians, I had a thorough conviction that every syllable I had stated in that document was most religiously true: I thought so then, and I must say (though I may be mistaken), that I think so still, even in the face of the bold assertions which Dr. Johnson has made in the last number of your journal.

I have written a statement of the facts relative to this subject, but for the moment, at least, I will defer sending it to the press. Were I to do so now, it is more than probable that it might be the means of preventing the publication of those valuable Trinidad documents, which contain such a mass of important information. But, independent of this, though Dr. Johnson has stated his charges distinctly enough, I am still left in the dark with respect to the real nature of the facts by which these charges are to be proved; when we know what the proofs are, we shall then be more able to judge of their value. Dr. Johnson, however, has promised to publish the said documents within fifteen days from the date of his letter. When this

is done I pledge myself, on the other hand, to lose no time in producing sufficient evidence to prove that all I have stated, and perhaps even a great deal more, is perfectly correct. By inserting this in the next number of your journal, you will oblige, sir,

Your most obedient servant,
W. M. STEVENS, M.D.

Dec. 14, 1831.

TREATMENT OF CHOLERA.

THE following official letter has been addressed to the Chairman of the different Medical Boards throughout the kingdom.

Central Board of Health, Council-Office,
Whitehall, Dec. 13, 1831.

Sir,—Agreeably to the intimation given by this Board in the concluding paragraph of their circular, dated 14th ult., I have the honour to transmit the subjoined “sanitary instructions for communities supposed to be actually attacked by spasmodic cholera,” with some observations on the nature and treatment of the disease, drawn up by Drs. Russell and Barry.

Every individual being deeply interested in the preservation of the public health, it is the bounden duty of all to endeavour to arrest the spread of disease at its very commencement. In order to attain this important object—

1st. The most efficient arrangements should be made by the local boards of health, and other authorities, to obtain the earliest and most correct intelligence of every suspicious case which may occur within their jurisdiction.

2d. All unnecessary communication should be prevented, as far as possible, between the infected and the healthy.

3d. As space, cleanliness, and pure air, are of the most vital consequence, both to the recovery of the sick person and to the safety of those about him, the patient labouring under spasmodic cholera should either be placed in a separate, well-ventilated apartment of his own house, if it afford such accommodation, and be attended by as few persons as the circumstances of his case will admit, or be induced to submit to an immediate removal to such building as may have been provided for the reception of persons whose circumstances will not afford the advantages at home, of space, air, and separation from the healthy.

4th. When an individual shall have been attacked with this disease, and placed under the most favourable conditions, as already pointed out, both for the recovery of his own and the safety of the public health; the room or apartment where he may have

been attacked, and from which he may have been removed, should be purified by scrubbing, lime-washing, free ventilation and fumigation by heated sulphuric acid and common salt, with black oxyde of manganese, or the same acid with nitre; or, when these materials cannot be obtained, by strong vinegar thrown upon heated bricks. The bed, bedding, and clothes, should be immersed in water, washed with soap, and afterwards fumigated as above.

5th. To correct all offensive smells, chloride of lime may be applied; but great caution is recommended in the use of this material, its fumes continued for any length of time having been found highly prejudicial to health—more particularly in delicate persons.

6th. A number of steady men, proportionate to the district in which they are to act, should be appointed to lime-wash and purify, as ordered above, under the direction of medical authority, such apartments as may be pointed out by the inspectors of the local board.

7th. Those who die of this disease should be buried as soon as possible, wrapped in cotton or linen cloth saturated with pitch, or coal tar, and be carried to the grave by the fewest possible number of persons. The funeral service to be performed in the open air.

8th. It is of the utmost importance to the public health that an improved diet, and flannel clothing, at least flannel belts and woollen stockings, should be given to the poor. No person should ever allow himself to sit down and get cool with wet feet: indeed the most particular attention should be paid to keeping the feet dry and warm. Repletion and indigestion should be guarded against; all raw vegetables, acescent, unwholesome food and drink avoided. Temperance should be most rigidly observed in every thing. In short, no means should be neglected which may tend to preserve individual health. The neglect of any or all of these cautions would not of themselves produce the specific disease called spasmodic cholera; but such neglect would most assuredly dispose the individual living in an infected atmosphere to be attacked by this disease, when most probably he might otherwise have escaped.

The most effectual means by which this disease may be prevented from extending, is to enable the poor, who are generally the first attacked, to oppose to its influence, as far as practicable, those ameliorations in diet, clothing, and lodging, which public and private charity will, it is hoped, not fail to produce.

Observations on the Nature and Treatment of the Disease, drawn up by Drs. Russell and Barry.

“Of the two great classes of functions

performed by the organs of which man is composed, one only is attacked in this disease. The operations of the senses and of the intelligence are either left untouched, or are affected but in a secondary manner.

Those functions, on the contrary, by which existence as a living being is preserved; those complicated powers, by means of which we are for ever appropriating and converting into a part of ourselves portions of the matter around us; are all and at once deranged by the attack of this terrible malady. Nutrition is annihilated; respiration becomes difficult, irregular, and inefficient; the involuntary muscles no longer perform their task; the voluntary are drawn into contractions by other powers than the will; the blood ceases to circulate; its physical properties are altered; its serous portion is suddenly thrown out upon the intestinal mucous surface of the body; the secretions are all arrested; and animal heat is no longer produced.

Under such rapidly destructive, and almost universal derangement of function, the most energetic efforts should be directed to reproduce what the disease has rendered nature unable to keep up—viz.

1st. Fluidity, heat, and motion in the blood.

2dly. Regulated action in the voluntary and involuntary muscles.

Lastly, but above every other consideration, renewed energy in the nervous centre, the source of all vitality and function.

No remedy at all approaching to the nature of a specific has been as yet discovered for this disease. In fact, no one mode of cure can be usefully employed under all the circumstances of any disease. The grades of intensity, and the grouping of the symptoms with which spasmodic cholera makes its attacks, vary with the conditions of the subject; its treatment, therefore, must vary with these grades and conditions.

The leading preliminary symptoms generally are, either diarrhœa, spasms, apoplectic vertigo, with nausea, imperfect vomiting or various combinations of these symptoms.

When the diarrhœa affords time for distinct treatment, it ought to be arrested at once by the most prompt and efficient measures;—by opium in moderate doses; astringents; local bleeding by leeches, if the subject be plethoric; by cordials and sulphate of quinine, if there be cold sweats; by confining the patient strictly to bed, and keeping up heat; by diet; by emetics.

Should spasms be the first and leading symptom, subnitrate of bismuth, cupping along the course of the spine, cordial, and antispasmodic medicines, opium, frictions, and dry warmth, are indicated.

But when the patient is suddenly seized with vertigo, nausea, coldness, loss of pulse, blueness of the skin, shrinking of the features

and extremities, with more or less watery discharges and cramps; constituting an aggravated case of the worst type; whether this state shall have come on without warning, or shall have supervened upon either, or both of the preliminary sets of symptoms already mentioned, time must not be wasted upon inert measures. Such a patient will inevitably perish, and within a very few hours, if the paralysed vital functions be not quickly restored.

Let him then be immediately placed between warm blankets; and should no medical person be at hand, let two table-spoonfuls of common kitchen salt, dissolved in six ounces of warm water, be given immediately, and at once, if he be an adult. Let dry and steady heat be applied along the course of the spine, and to the pit of the stomach (if no other means be at hand), by a succession of heated plates or platters. Let the upper and lower extremities be surrounded with bags of heated bran, corn, ashes, or sand, and assiduously rubbed with a warm hand, and a little oil or grease to protect the skin. Energetic, complete vomiting, will probably be produced by the salt; and perhaps bilious purging, with tenesmus.

Should a medical man be on the spot, a moderate bleeding, if it can be obtained, would be desirable, previously to, or immediately after the administration of the salt, or of any other emetic which may be preferred.

The extensively deranged action of those organs, whose nerves are chiefly derived from, or connected with, the spinal marrow; the anatomical characters found about that great source of vitality, after death, in many cases of this disease; together with the success stated by Dr. Lange, Chief Physician at Cronstadt, to have attended the practice mentioned below, founded upon these views, in twelve out of fourteen aggravated cases, fully justify the following recommendation.

In cases such as those just described, let the actual cautery be freely applied to one or two, or more places on either side of the spine, as if for the purpose of forming good-sized issues. Should the heated iron have produced any excitement of the nervous power, and the salt emetic have caused any portion of the bile to flow through its proper duct, a great step will have been accomplished towards recovery from the stage of collapse. Cordials and opiates judiciously administered; sinapisms and other external stimulants; mercurials, with mild aromatic aperients, which the intelligence and activity of British medical practitioners will not fail to adapt to the actual circumstances of each case, will conduct the patient safely to the stage of re-action.

The organs, during the collapse of this disease, probably owing to deficient vitality, often give no indication of having been acted upon by repeated doses of certain

powerful medicines, which, under other circumstances, would have produced the most pronounced effects. It is therefore suggested, that this temporary insensibility of the system should not inculcate the administration of such repeated quantities as could, by accumulation, when the organs begin to recover their vitality, give rise to unfavourable results.

Thirst being a most distressing symptom of this disease, the quality and the temperature of the drink should perhaps be left to the choice of the patient; but the quantity taken at a time should not exceed four ounces, and should be acidulated with nitrous acid, if the patient will bear it.

Should the disease prove extensively and rapidly epidemic in a large community, it would be prudent to establish stations at convenient distances from each other, where medical assistance and medicines might be procured without the risk of disappointment or delay. The details of these arrangements are left to the wisdom of local boards of health.

As the symptoms of the consecutive stage of feverish re-action in cholera differ but little, if at all, from those of ordinary typhus, except perhaps in the greater rapidity with which they but too often run to a fatal termination; and as this kind of fever is treated in no part of the world with more success than in England, the entire management of this stage of the disease is left to the zeal and science of the profession at large.

Attentive nursing, and assiduous well-directed rubbing, are of the utmost importance; a strictly horizontal position, however, must be maintained until the heart shall have, partly at least, recovered its action. An erect or even semi-erect position, during the collapse, has been often observed to produce instant death. Warm baths, therefore, for this and other reasons, are worse than useless; evaporating fluids, and indeed all moisture applied to the skin, seem to be contra-indicated for obvious reasons. Hot air baths, so contrived as to be applicable in a recumbent posture, and admitting access to the patient for the purpose of friction, may be of use."

I have the honour to be, sir,

Your most obedient servant,

E. STEWART, Chairman.

MAGENDIE'S DESCRIPTION OF CHOLERA.

A FEW days ago, Magendie, in returning to Paris, from his visit to Sunderland, was asked, by a distinguished physician in London, what he thought cholera?—"I think (said Magendie) that it is a disease which begins where others end—with death."

CHOLERA—VARIETIES.

IN a letter from Dr. de Karttsoff, dated St. Petersburg, October 28th, he states that cajepout oil was fully tried at Astrachan, without being attended with any benefit.—*Gazette Médicale*.

The same writer asserts, that the muriate of soda completely failed at St. Petersburg, in all the cases wherein it was tried.—*Ibid*.

Two women, who were suckling, were seized with cholera: two young dogs were fed on their milk; both animals died within twenty-four hours, having convulsions.—*Ibid*.

It is not true that chlorine failed to counteract the infectious principle of cholera at Moscow and St. Petersburg.—*Ibid*.

The offer of 25,000 roubles, by the Russian government, for a cure of cholera, has already produced 125 essays, pointing out infallible remedies. Unluckily almost all of these have been discovered in the closet of the writers, and never tried in the sick chamber.—*Ibid*.

In consequence of a case of poisoning, at Paris, having, in the first instance, been declared to be cholera, the Prefect has addressed a circular letter to the Mayors of the provinces, directing them to be on their guard against similar mistake or imposition.—*Ibid*.

LECTURES
ON
THE THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

PART I.—LECTURE XII.

Inflammation—(continued.)

At the last lecture, gentlemen, I spoke of the usual terminations of inflammation, as they are called; and I likewise spoke of several other effects,—consequences of inflammation, which are observed, but still are not all among those usually mentioned by old authors—they are only recently enumerated terminations, viz. hypertrophy, or over-nourishment — atrophy, or defective nourishment, and consequent increase or decrease of size; induration, softening, and transformations of structure.

I mentioned that those which are usually called the terminations of inflammation, and those other changes which frequently are its results, may take place, at least many of them, without inflammation; that although they generally arise from inflammation, yet they may occur without it, or at any rate with an exceedingly slight degree of it, and be out of all proportion to it.

Mortification independent of Inflammation.

Having spoken of ulceration and induration, and other things, as occurring occasionally without inflammation, I was speaking, at the close of the lecture, of mortification as occurring under similar circumstances, or at least with an exceedingly small degree of inflammation, not as the result of inflammation, but only an accompaniment, if there be any at all. When the chief vessel of a part is obstructed by a ligature, this will frequently produce mortification of those parts below to which the ramifications of the blood-vessel are distributed. Sometimes the legs will mortify from bad food, and the most common kind which produces this effect is diseased grain,

Spurred rye, or *ergot of rye*, as it is called, causes mortification, I believe, in all animals, though the quantity requisite for that purpose varies in different species. If an animal live upon this, there is sometimes a reddish fluid observed to ooze from the nostrils, sometimes there is violent pain of the extremities, and sometimes there is also heat and redness, actual inflammation, and then gangrene takes place. Frequently, however, it does not cause heat and redness, but a withering of the part, which will dry and look like the extremities of a mummy. These become cold, dry, shrivelled, and withered; and at the same time, diarrhoea, vertigo, convulsions, and delirium, very frequently take place. There is internal inflammation frequently induced in the alimentary canal, but the extremities generally mortify, and look as I have stated. I need not say that this state is not contagious. It is common in France, and formerly it was common in England; and when the latter was the case, the cause appeared to be diseased wheat.

I believe that other grain, diseased in a similar manner, has a similar effect; the ergot of maize in Colombia is said thus to act: at least it will cause the hair to fall off, sometimes the teeth to drop out, and frequently induces sudden death. It so happens that brutes are exceedingly fond of it; they will therefore frequently gorge themselves with it, and then die suddenly. It was observed that the hens which ate of it in Colombia discharged their eggs prematurely before the shell was formed; and it is imagined, at any rate it is possible, that the fact of its occasioning the abortion of eggs in hens, led persons to employ it in the case of the human subject, for the purpose of emptying the uterus speedily. I may mention that these properties appear to be destroyed by cold, for it is found that if this diseased maize be carried over cold mountains—over the Paramos, it may afterwards be eaten with impunity—so at least it is said.

Mortification will sometimes occur, not from inflammation, but from ossification, it is said, of the minute arteries. Some say that

mortification will arise from the ossification of the larger and more distant arteries, but certainly it is generally believed to be sometimes occasioned by the ossification of the minute arteries. Cruveillier, by artificially inducing a similarly obstructed state, produced the same effect. He injected mercury into the arteries, so as to fill the capillary vessels with it; and when an obstruction was thus produced, mortification was the consequence.

It is possible, that, when extreme congestion of blood takes place in parts, and continues for a length of time, it may produce mortification, in some measure from the blood coagulating in the minute vessels: nothing is more likely than this.

The mortification which arises from an obstruction in the minute vessels, induced by an ossification of the minute arteries, most frequently takes place in males, and especially in the old and voluptuous. Generally the gangrene is dry, the part shrivels up, and the state is preceded by very great pain. There are two varieties of dry gangrene—the pale and the black. Some believe that mortification never occurs without inflammation, but I do not think this is proved. Many things are asserted in medicine without, I think, sufficient proof, and occasion a great deal of trouble to those that follow the asserters, by making it necessary for them to prove that the assertions are not true. I do not mean to apply this remark to the case before us, because it is only an opinion, but what I complain of is too common an occurrence. I do not know that it is proved that mortification is always preceded or accompanied by inflammation, but if it be, still it is often not by any means in proportion to the inflammation. You see the severest mortification with the slightest or no inflammation, and you see the most intense inflammation without inducing mortification. Some inflammations have a great tendency to end in mortification. The inflammation of glanders in the human subject, though not more intense than many other inflammations of the face, nevertheless has a great tendency to induce mortification.

With respect now to all the effects of inflammation, and those changes which, though they frequently are its effects, yet sometimes appear not to be exactly so, I may mention that induration is generally the result of slow inflammation, but that softening is continually seen without any signs of inflammation. Hypertrophy—over-nourishment, like induration, is, I believe, generally the result of slow inflammation; but atrophy, the wasting of a part, is frequently seen without inflammation. I may mention that in phthisis the heart is usually small, flabby, and perhaps shrivelled, though not previously inflamed. The transformations of one structure into another which is natural to the body, though not to the individual part, are certainly more frequently the result of inflammation than not; but the new formations, those

which are not analogous to any thing already existing in the body, are far more frequently not the result of inflammation. Continually there is not a vestige of inflammation to be found during their production; they rather appear to be alterations of action than the result of an actual inflammation. The part is entirely altered, a new product is formed, but that is all: it does not appear to be the result of inflammation. When inflammation does accompany those new formations which are called non-analogous, such as encephaloid disease, or cancer, it is often only an accompaniment, and not their cause. Sometimes it is only the predisposing cause: inflammation throws a part into a predisposition to disease, and then a fresh disease is set up. That these things are not the result, at any rate, of mere inflammation, is shewn by the fact that ten times more inflammation continually occurs without such effects being induced. If there be inflammation which goes on *pari passu*, still you are not justified in saying that they are the result of inflammation; and in these affections, if you employ the most vigorous antiphlogistic measures, in the most persevering manner, still you do not cure the disease; you scarcely, or not at all, control it. The morbid tendency to the morbid process is continued, and the disposition to it would often appear to excite the inflammation—the inflammation to be the consequence of the disposition to the disease, and not the disposition the result of the inflammation. Indeed, inflammation in many cases is only the ultimate effect. The new formations irritate the part so much that inflammation is excited, and an attempt is made by nature to discharge the formation. In this way scirrhus has sometimes been completely separated by nature from the body.

The existence of tubercles in the lungs, which are new formations, not analogous to any thing in the body, cannot be the result of mere inflammation, because you see inflammation occurring every day without them, and you see them produced without signs of inflammation. Occasionally, people who are disposed to this disease will, by having the lungs thrown into an unhealthy state by inflammation, become the subjects of tubercles from that time, because any thing which throws the body out of health gives a predisposition to disease of some kind or other, or if there be a predisposition, it is increased, and the new disease is excited. If you feed a rabbit badly, keep it in a damp place, and in the dark, so that it has a deficient quantity of light and heat, and unwholesome food, it may become the subject of tubercles; a new depraved secretion takes place, but this is not the result of inflammation. If you were to give an animal stimulants, you might produce an inflammatory state of the

whole body, or of any organ, but not induce tubercles. Certainly the attempt to explain every thing by inflammation appears to me to be an absurdity, and I am happy to find my opinions on this subject coincide with those of Andral, who in his *Morbid Anatomy* argues successfully against Broussais, that inflammation is not always the cause of tubercles; that it occurs continually without inflammation; and that when it does occur as the consequence of inflammation, it is not so much the result of the inflammation itself as of the part being thrown out of health, and thus easily becoming the victim of the predisposition to tubercle. These are all the observations that I have thought it necessary to make, gentlemen, respecting the symptoms and effects of inflammation, and I shall hereafter speak of all changes of structure in general.

Predisposing Causes of Inflammation.

I shall now consider the causes of inflammation; commencing with the remote; and of the remote causes, the predisposing, of course, come first to be considered. The first circumstance predisposing to inflammation is the sanguineous temperament, and the next may be considered high health. In the sanguineous temperament there is generally a great quantity of blood, at any rate there is a large quantity in the minute vessels, so that the blood circulates to a great extent—the pure blood itself—throughout; the body is readily flushed, and vessels readily contain blood which should not: the circulation is full and rapid. I need not say that high health must have the same effect. A person in a high state of health has a florid colour, there is an increased quantity of blood circulating throughout the body, and to a great extent. Besides these two general circumstances of the body, the same occurrence may take place locally. There may be a local sanguineousfulness—a local fulness of blood, and that may predispose a part to inflammation. The face is certainly more supplied with blood than any other portion of the surface of the body, and consequently when exanthematic affections take place, such as measles and small-pox, most of them affect the face sooner than any other part of the surface, the inflammation which occurs there is severer. The same thing will occur from a particular period of life. In children the circulation appears most vigorous in the head; what is called “determination of blood to the head” takes place, and all that is meant by the term is, that more blood proportionately is circulating there than in other parts. In youth the greatest determination is towards the chest; and in the middle period of life and afterwards, it is in the abdomen. Hence children are particularly disposed to hydrocephalus, to inflammation of the arachnoid membrane of the brain, to cerebral affections, and are con-

tinually having fits—continually having affections of the head; and, consequently, a large number of children die of acute diseases of the head. Hence, too, children particularly have epistaxis. Persons in youth—those who have passed the period of childhood, are certainly more subject to all affections of the chest, to all thoracic inflammations, and to inflammatory spitting of blood. It is adults particularly who have inflammation of the stomach and intestines, both acute and chronic, especially chronic inflammation of the stomach and of the liver—indeed, inflammation and congestions, and structural changes of all the abdominal organs.

Seasons and climates will operate in the same way, by exciting either general or local fulness. Pulmonary inflammation is more common in cold climates, and likewise in the winter and spring; whereas in hot climates, and in the autumnal season of temperate climates, hepatic inflammation is most common.

Occasionally a part will acquire an increased excitability from a previous injury; and this is remarkably shown in the head. If a person have once had a severe injury of the head he may afterwards suffer from a slight cause—a cause which scarcely would have disturbed him before. I saw a person who had had a fracture of the skull, and for many years afterwards he would become completely delirious on taking a glass of spirits. This is an occurrence indeed that I have frequently seen. I very well recollect the case of a man who laboured under rheumatism of different parts of the body, and among others of the scalp, but he had suffered severe fracture of the skull some years before, and the mere excitement of the external part of the head was sufficient to excite it internally, so that he had violent delirium from mere trifling rheumatism of the scalp. Previous inflammation from any cause disposes a part to be inflamed again. Various causes, of an opposite tendency, will also have the same effect. Bad air, copious evacuations, bad food, depression of mind, fatigue of body, fatigue of mind, the frequent exhibition of mercury, an exhausting climate, and previous disease of any kind, will also dispose to inflammation. While all these predisposing causes, however, induce inflammation, its character is totally different according to the nature of the cause. The inflammation induced by the first kind of causes I mentioned is active and tonic; whereas the inflammation disposed to by bad food, bad air, depression of mind, and so on, is either passive or atonic—the inflammation itself is of a passive character, or there is not sufficient power in the system to carry it on, to get the patient well through it, or produce a healthy secretion of pus, if pus be produced. Hence the character of the inflammation varies according as the predisposing cause is one which gives

strength, high health, and excitement, or one which destroys health and strength, and gives a tendency only to an unhealthy excitement.

Some of these latter causes, as the defect of heat and the defect of food, act as predisposing causes to inflammation without producing any debility, or any atonic character of the inflammation. If a part be exposed to cold, it becomes more affected afterwards by a given degree of heat;—if a person be deprived of food, then, when a small quantity of food is given him, and of the weakest character, it will produce an excitement which strong food and a large quantity only would have produced before, and therefore some of these predisposing causes—a defect of heat and a defect of food—may act also by rendering the part more liable to be affected by stimulants; for stimulants act according to circumstances that went before them. According to the first, so is the second, and all that is requisite is, for there to be a great disproportion between the two. It is no matter whether the first is very defective, or the second is very great; for the effect is in proportion to their *relative* intensity, and therefore parts that have been exposed to cold, become violently inflamed if they be exposed to a moderate heat; and a person, who has been starved, has been known to become delirious merely by taking a little real broth. Many of these causes, however, produce a cachectic state of the constitution; and then inflammation, if it occur, is of a corresponding character.

Exciting Causes.

With respect to the exciting causes, we may mention, in the first place, a local stimulus, be that stimulus mechanical or chemical, or what is properly called a stimulus, independent of mechanical or chemical qualities, such as alcohol. The effect of all stimuli, as I have just now said, is not dependent upon the positive degree of force, but upon the difference between these stimuli and the strength of those which preceded them. Every body knows the danger of going from cold to intense heat.

Besides local stimuli, whether mechanical, chemical, or true stimulants, the depression of stimulation in one part will cause an inflammation in another. From having the excitement altogether exceedingly depressed in the feet, by a person getting wet through, and sitting with wet shoes, there will be such increased activity at a distant part, that inflammation may occur, so that many persons always have a sore throat or inflammation of the chest or eyes, if they get wet through, or have wet feet. This application of cold, depressing the action of one part and thus producing an excitement in another, depends very much for its effect upon the previous excitement. If the feet, for example, have been already hot—if they have been heated, and are in a

state of perspiration—then the application of cold produces so great a depression, that the inflammation of the throat, for example, or in the chest, will be so much the greater. Cold, within certain limits, is found to be more injurious in producing distant inflammation the more partially it is applied; but cold will itself, I believe, directly induce inflammation exactly as great heat will do. When we are exposed to cold air—when exceedingly cold air is passing through the nostrils, the nose will run; and it has been found experimentally that cold will really induce the same appearances, in the minute vessels, as heat, and as absolute stimuli. Nothing is more common than for rheumatism to be felt in the shoulders, or for an inflammatory pain to be felt in the ear, when cold air is blowing upon these very parts.

Thus, it appears, I think, that cold may induce inflammation in three ways: in the first place, by rendering the body liable to be exceedingly excited by the stimuli that come afterwards—by depressing the action so much, that when the stimulus of increased temperature is applied, the effect of this is tenfold increased; in the second place, it would appear to act by depressing the action in one part, and thus exciting a correspondent excess of action in another; and thirdly, it appears sometimes to act immediately and directly, by exciting inflammation. I think we have instances of all this:—first, when a person goes from the cold into a warm room, you will then see his face become very red—become exceedingly hot, and frequently he will cough violently, and a catarrh will be set up; in the next place, we see persons have inflammation of the eyes, nose, mouth, throat, or chest, from their feet getting wet and cold; and thirdly, we continually see pain in the ear, rheumatism of the shoulders, and the nose running, when cold air is applied to these very parts.

I believe that sudden refrigeration, and the sudden application of cold after excitement, is more frequently a cause of inflammation than the application of heat after cold. The greater number of cases of inflammation that one sees, are instances where persons have become suddenly cool—perhaps have got wet, as well as suffered the application of merely cold air—when they were over-heated and fatigued. A rigor is frequently induced, and a state arises which is soon followed by inflammation. The effect of sudden refrigeration, therefore, is greater in proportion to the previous excitement; it is also greater if it be partial than if it be general; and it is always greatest if there be much sweating and exhaustion; and, indeed, I may mention that sometimes fatal results have instantly occurred. Many persons, from taking ice when they have not only been hot, but sweating and exhausted, have dropped down dead. The account of Alexander the Great bathing in the Cydnus when exceedingly hot

and exhausted, after great fatigue, is well known: he nearly lost his life by it. However hot the body may be, there is little danger, comparatively, if it be not fatigued. The Russians go from the vapour bath and roll in the snow.

The effect of cold applied to the body is much increased by damp: very often persons do not suffer from the application of cold till dampness is conjoined with it. It may act simply by increasing the cold—by lowering the temperature still more; but I cannot help thinking that it injures to a greater extent than this will explain—that it is injurious out of proportion to the greater diminution of temperature which the dampness occasions. Many persons are not so strong by any means in damp weather. It is possible that it may act by conveying the electricity away in too great a quantity. In dry weather we are all active and vigorous; but in damp weather there certainly is a degree of languor—an inaptitude for action, both of body and of mind, which most persons notice.

The effect of cold upon the body is much increased by sleep. In sleep the powers of the body are less, the pulse is slower, the heat is not so high, and all noxious agents are less withstood. It is a common remark, that if a person go to sleep in a draft, he is sure to catch cold; whereas, if he contrive to keep awake, he very likely escapes. At any rate, every body knows that if a person fall asleep when exposed to cold, he is almost sure to suffer.

Cold, too, appears to be more dangerous when applied to the back part of the body than to the front. I imagine there is less power there than in the front. Persons will escape if a little draft come in the face, whereas, if it come to the back of the head or neck, they almost always experience ill effects.

Inflammation is sometimes excited as a sympathetic occurrence. But when I say that inflammation is excited by sympathy, I do not explain the fact; I merely express the fact. When one eye is inflamed, the other, without any external cause, may also become inflamed; and this is called a sympathetic result—it is said to occur by sympathy. It is common, if the head be inflamed in a child, for the abdomen to become likewise inflamed—either the intestines, stomach, or liver, and *vice versa*. It is of the highest importance in practice to be looking out for this circumstance, or you may be treating only one inflammation when two exist. If you be asked the nature of a case of this description, you will be fully justified in saying that is complicated—that there is inflammation in two parts, though you told the friends with truth at first, that there was inflammation of only one.

Metastasis is also another mode in which inflammation occurs. When inflammation of the parotid glands ceases in mumps, the

brain will become inflamed, or, what is more common, the testicles, or one testicle; and this inflammation, I may mention, often affords an illustration of atrophy as the result of inflammation. It is very common, indeed, for a testicle, when it has been inflamed after mumps, to waste away, so that nothing will be left but the membranes. In gout, metastatic inflammation continually occurs. When the gout ceases in an extremity suddenly, it is very common for inflammation to take place in the head of an apoplectic nature, or for inflammation to occur in the stomach or intestines.

We occasionally have inflammation induced from the introduction into the circulation of an unhealthy or acrid matter. If pus, or any diseased secretion, be absorbed, it is very common to find a deposition at a distance from the part in which it was originally formed. We have at a distance a deposition of pus, or of lymph, in the various viscera, in the cellular membrane, and even in the secreting cavities, or inflammation and disorganization without deposition. Probably inflammation of the veins takes place, and perhaps the pus formed in them causes such an inflammation in distant parts, that new pus, lymph, and other things, are there produced. But such is the fact, that if pus, or an acrid secretion, get into the circulation, these results take place—if not distant inflammation, at any rate a deposition of pus, or lymph, debility, great irritation, and a sallow hue of the countenance.

It has been said, that the predisposing causes to disease will sometimes become exciting, merely by their continuance and increase, so that no exciting cause is necessary. This may be the case with regard to fulness of blood. A part may become more and more filled with blood; congestion or determination of blood, whichever it is called, may increase till at last inflammation occurs; or a state of apoplexy, if it be the head that is affected, may be produced without any actual exciting cause. However, in specific inflammation this cannot be the case. I suppose that all the predisposition in the world would not give a person the small-pox, unless the exciting cause were applied.

Such are the observations which I have thought it necessary to make respecting the remote causes of inflammation.

Proximate Cause.

We will now consider the proximate causes of inflammation—that which is essential to the existence of the disease—in fact, the actual state of the parts in inflammation. In the first place I think it is a fact, that in inflammation blood is found in vessels which are not designed to contain it—blood enters vessels which in a healthy state contain no blood; and, in the next place, those vessels which naturally contain blood are enlarged and contain more blood than they ought to do. John Hunter made an experi-

ment to prove the latter circumstance. He says, "I froze the ear of a rabbit, and thawed it again; this excited a considerable inflammation, an increased heat, and a considerable thickening of the part. This rabbit was killed when the ear was in the height of inflammation, and the head being injected, the two ears were removed and dried. The uninflamed ear dried clear and transparent; the vessels were seen distinctly ramifying through the substance; but the inflamed ear dried thicker and more opaque, and its *arteries were considerably larger.*"

Now that vessels have undoubtedly a contractile power, is shewn both in the large vessels and in the capillaries. I do not know how the action of the capillaries, or of the arteries, can contribute to the circulation in health, but it may alter the circulation, according to the larger or smaller size of the vessels—accordingly as they are constricted or dilated, so that there may be more or less blood in the part itself, and in those parts to which these vessels lead. The whole of our present knowledge upon this subject, together with my own opinions upon it, you will find, like the circumstance of the coagulation of blood, in a note to Blumenbach's Physiology, upon the circulation; I will not, therefore, dwell upon it. Notwithstanding it is quite certain that the arteries and capillaries have this power of contraction—notwithstanding I doubt it can assist in furthering the circulation, although it may and every day does certainly alter it—I cannot conceive that this increased action is compatible with increased redness and fullness; I cannot conceive that, in inflammation, when a part is redder and fuller than it should be, there can be increased action—by which I mean, that the vessels can be more constricted and more dilated, than before; for if they were redder at the one moment they would be paler at the other—the one would counterbalance the other. But whether there is an increased action or not, it would appear, at least, that there is a diminished motion of the blood in inflamed vessels. There appears to be a retardation of the motion, and such retardation is commensurate with the inflammation. This has been shewn by Vacca, Lubbock, Bichat, Allen, Dr. Wilson Phillip, and recently by Dr. Hastings, under the microscope; and still more recently, Gendrin has confirmed the observations which Drs. Philip, Hastings, and others made. They applied mechanical violence, heat, cold, and ammonia, and at first they perceived by the microscope that the blood moved more rapidly; there was an increased velocity, and a contraction of the vessels was seen, and a paleness. This is what we should expect from what is called increased action. After the increased action, after the contraction of the vessels, the motion became slower, the course of the blood was retarded, the vessels became dilated, and inflammation appeared; in this

they all agreed. If the part were already inflamed and then a stimulus was applied, this stimulus had the immediate effect of quickening the blood's motion, constricting the vessels, and then the inflammation ceased. If the stimulus were applied very violently, so as to produce most violent action, and extreme rapidity, of course this lasted a shorter time; and the second stage—that of slow motion, dilatation of the vessels, and inflammation—came on sooner. By applying the stimulus very violently, the second stage might be made to come on immediately. It is said, however, by them, that the oil of turpentine differed from all other stimuli, by causing the first stage only—it was not followed by the second; and if it were applied in the second stage, it always removed it; while common salt, on the contrary, caused instant dilatation—caused instantly the second stage. It would appear from these experimenters, who are very numerous, reside in different countries, and have succeeded each other, and each repeated the experiments with a view to ascertain whether his predecessors were correct or not—it appears from them, that, in the inflamed part, the blood moves more slowly, that the vessels are dilated, and that by applying stimuli you cause the vessels to contract, the blood to move more rapidly, and then the inflammation ceases for a time, till the blood is retarded again, and the vessels dilate. One would not expect that cold would have exactly the same effect as stimuli, but such was found to be the case. We all know, that if parts are cold they become reddish, as is seen in the nose and cheeks in winter: they grow dark—grow more and more red, till at last they become of a mulberry colour; and perhaps, such congestion takes place that gangrene may occur.

You will find, on this subject, very excellent information in Dr. Hastings's work on Bronchitis; in the introduction to that work he treats this subject very fully; and since he published, Gendrin, on the continent, has repeated the experiments with precisely the same results.

You will find some objections to these results—from experiments made by himself—in Dr. Thomson's work on Inflammation (and, by the way, I may mention that that is a work which every person should read, and not only read, but study carefully. I think it is a much better book to read on inflammation than John Hunter's); but the objections he starts are fully answered by Dr. Hastings. Dr. Thomson says that you have, in inflammation, increased action and motion; but Dr. Hastings answers, that Dr. Thomson himself, in some cases of inflammation, saw a slower motion: and that he speaks of seeing red globules in the parts where the blood was in rapid motion, and must have made a mistake, because in the blood of parts inflamed you will not discover red globules at all, as they are mingled together or broken

down. Dr. Hastings concludes, therefore, that in the cases in which Dr. Thomson saw rapid motion, there could not be inflammation, but that he saw the state which precedes inflammation.

The large vessels going to an inflamed part are frequently felt to throb. If there be a whitlow upon the finger, the digital artery behind it throbs violently; and in inflammation of the face the angular artery may be felt doing the same; and in the case of headache the temporal artery is in a similar condition. This, however, is no proof of increased action in them, for the same occurs in an aneurism, or a dilated artery. When an artery is dilated, though weakened, softened, and unable to act as it did before, you will find it throb violently, simply on account, I presume, of its increased capacity. However, in that kind of inflammation which is called passive, and which some say is not real inflammation, but mere congestion, this enlargement of the surrounding vessels is wanting, so that you have not this throbbing of the large vessels.

These appear to be the chief facts ascertained regarding the state of parts in inflammation; but there are many other particulars. In the height of inflammation the open extremities of vessels certainly are affected with spasm; they will not pour forth fluid as they did before. When a mucous membrane is inflamed, its secretion will stop; the secretions of an inflamed part at the very height of inflammation cease, or at least are greatly diminished, so that one must suppose that there is a spasmodic and constricted state. Perhaps the word spasmodic may be objectionable; but a constricted state of the extremities of secreting vessels appears to exist in inflammation. Yet, however, far more changes than these take place; the blood is buffed and cupped, it contains more fibrin, and this is thinner than it ought to be. The blood in the small vessels becomes homogeneous, broken down, the red particles are indistinct, and sometimes flocculi are seen in it which are not visible in the immediate surrounding capillaries. When a part is mortified, then the blood around it is yellow, its various constituents separate, and it is evidently in a state of disease.

Ratio Symptomatum.

With respect to the explanation of the symptoms of inflammation. The *redness* is very easily explained, from the existence of blood in vessels that ought not to contain it, and the existence of too much in those which should contain it. The *swelling* will arise from the same circumstance, and also from the increased secretion that is going on around. The *pain* will arise from fulness, and from the tension of all the parts; this is produced by the accumulation of blood, and by the excessive secretion around. But

the pain will also arise probably from an increased degree of sensibility. There is, in every case, the pain from fulness and tension; but the pain is felt far more severely, on account of the morbid sensibility. With respect to the *heat*, I presume it arises from the increased momentum of blood in the part, the increased quantity, and which is still circulating. If the same quantity of blood were in the part, and motionless, of course the part would grow cold; but as the blood which is in it is far greater than usual, and still moves on so as to come round to the lungs, a greater number of changes giving rise to heat must take place. There is far more blood in the part than there should be: and as heat appears to be connected with the existence of blood circulating, coming round to the lungs and undergoing chemical changes—in proportion to the quantity of blood circulating there must be increased temperature. If the blood cease to circulate, or the circulation becomes languid, so that it does not undergo a regular chemical change, then of course the part becomes cold. Momentum is composed of rapidity and quantity. The former is lessened, but the latter greatly increased, so that on the whole the momentum is greatly increased.

CLINICAL OBSERVATIONS

Delivered in the General Dispensary,

By MR. COULSON,

Dec. 3, 1831.

Hæmatocele and Hydrocele.

GENTLEMEN,—The case of hæmatocele on which you recently saw me operate, is deserving of your notice. The patient, John Vaughan, æt. 34, first laboured under hydrocele about eight years ago, since which he has had the water drawn off six times in all—five times by my predecessor, Mr. Lloyd, and once (on the last occasion) by a surgeon from the country, who was then on a visit at his master's house. The scrotum gradually filled again; and when it had attained its usual size, (30th of October) the patient requested a surgeon to tap him, and the operation was accordingly performed. The water which was drawn off was tinged with blood; and soon after the operation, the patient experienced great pain in the part, and the scrotum attained a large size, and became very black. Great constitutional irritation also supervened. On November 7th I first saw Vaughan, when he was then fast recovering from the effects of the effusion of blood which had taken place. Some discoloration of the integuments from the effused blood remained, and the removal of this I endeavoured to hasten by the use of stimu-

lating lotions, as spirits of wine and water, and vinegar and water. The scrotum was then very large. When all the blood between the tunica vaginalis and the integuments of the scrotum had become absorbed, I advised the patient to submit to another operation, to which he readily consented.

On November 17th I laid open the cavity of the tunica vaginalis, and removed rather more than six ounces of dark-coloured coagulated blood. There was a gentle oozing from some parts of the tunica vaginalis, but no distinct vessel could be seen. The tunica vaginalis itself was very much thickened, and there was an imperfect membranous septum going across the middle of it. A pledget of lint was introduced between the edges of the wound, to keep them open; the tunica vaginalis soon began to granulate, and the wound is at present nearly healed. No hæmorrhage, or any other unpleasant symptom, has occurred, and I hope a radical cure has been effected. The testicle, however, is much enlarged. The hæmatocele occurred in this case from the accidental puncture of a vessel during the operation for hydrocele; no blame is to be attached to the surgeon who performed it. The suddenness of the occurrence of this complaint is its characteristic feature; it comes on rapidly after a blow, or contusion to the part, or subsequently to the operation for hydrocele. When the blood is effused into the tunica vaginalis, you must pursue the plan of treatment which I adopted in Vaughan's case; when, however, it is simply effused into the cellular tissue of the scrotum, the application of leeches and cold lotions, with rest, will be in general sufficient to effect a cure. The two other forms of this disease, (viz. effusion of blood within the tunica albuginea, and into the cellular tissue covering the spermatic cord,) I have not seen. I will not, therefore, detain you with an account of them, but must refer you to Mr. Pott's work on hydrocele, in which they are fully described.

Hydrocele, with Hernia.

John Leeson, æt. 43, was admitted under my care November 20th, 1831. He has a hydrocele on the left, and a scrotal hernia on the right side, which enables you to observe the diagnostic marks of this complaint on the same patient. Coughing communicates an impulse to the hernia, but none to the hydrocele; and the spermatic vessels can be distinctly felt on the one side, and not on the other. Pressure makes an impression on the hernia, but none on the hydrocele; and when the patient lies down the hernia returns, but the hydrocele remains unchanged. You are not likely to confound these two complaints. I drew off a pint and a half of fluid, and should have performed

the radical cure, but he could not conveniently stay from his work.

Hydrocele.

John Reynolds, æt. 60, was admitted under my care, October 19th, 1831, with hydrocele. I had often tapped him; and the only remarkable feature in his case was the situation of the testicle. Instead of being placed at the back and lower part of the scrotum, it was situated in front. I therefore introduced the trocar, not in front, but at the side of the swelling, and thus drew off the water.

Disease of the Hip—continued from p. 293.

In disease of the hip, (to which subject I drew your attention at our last meeting) the parts entering into the formation of the joint, undergo, as you might expect, very considerable changes. The nature of these changes depends in a great measure on the extent of the disease, and on the constitution of the person attacked by it. The complaint which we have been considering is inflammation, shewing itself first in the cancellated structure of the head of the femur, and then extending to the acetabulum and parts in the neighbourhood of the joint. If the complaint occurs in a scrofulous subject, the inflammatory action will be very much modified by this state of the constitution. In scrofulous inflammation of bone, the earthy matter becomes absorbed, and the bone consequently softened, whilst the cancelli are filled with a yellow caseous matter, or a transparent yellow fluid. But the striking feature in this kind of inflammation is the absence of all secretion, or deposit of bone; whereas in simple inflammation, uninfluenced by the scrofulous diathesis, particularly when it becomes of a chronic character, bone is secreted in abundance. Mr. Langstaff, who has paid great attention to this, and, indeed, to every other department of pathological anatomy, says that he never saw a case of bony ankylosis in a scrofulous subject, and he does not believe that it ever occurs. The head of the bone is always changed in structure, and in scrofulous subjects it is much softened.

By the extension of the inflammation the ligaments of the joint become altered in their texture, loose, and spongy; the cartilaginous coverings of the acetabulum and femur are removed; and the two surfaces sometimes become firmly united. Ankylosis between the head of the femur and the acetabulum is the most favourable termination that can be expected of the complaint; for the only effect which remains is a certain degree of shortening, and impeded motion of the limb. In a few other cases the head of the bone is destroyed by caries, and the neck, or even the trochanter major, becomes ankylosed with the acetabulum, which, I think, would

have been the result in Dexter's case, which I mentioned at our last meeting, had she survived. In the majority of cases, however, the bone is dislocated, and either becomes ankylosed with the bone on which it rests, or the attempt at the formation of a new joint is set up. The bones of the pelvis often suffer very considerably in this disease, and the matter which forms near the joint often finds its way into the pelvis. Mr. Brodie mentions two cases in which the matter was voided by the rectum. In fact, in some cases the os innominatum is more extensively affected by the caries than the thigh bone itself. Rust, who has published a minute description of the unnatural direction given to the muscles in this disease, has also described the change which the bones of the pelvis undergo in their form and situation. The pelvis, he says, in those who have for a long time gone lame, is pushed upwards, the sacrum is flat and straight; in a few cases, however, it is more curved than in the natural state. The coccyx is bent strongly forwards, and the connexion of the last lumbar vertebra with the sacrum forms a right angle. The ileum of the affected side stands higher, and has in general a perpendicular direction, and more of a triangular form. The external surface is smooth, whilst the fossa appears more hollowed than usual. This hollowing probably depends on the action of the iliacus internus, which is greater than that of the glutæi. The horizontal portion of the pubis often seems lengthened, and lower than in the natural state, and the ischium is usually drawn outwards and forwards. The perpendicular direction of the foramen ovale is changed more to an horizontal one, and the opening assumes more of a triangular shape, the base of which is turned to the acetabulum. In consequence of the changed situation of the bones of the pelvis, its different diameters undergo an essential deviation from the natural state. The superior apertures of the pelvis are commonly somewhat oblique, and the pelvis broader on the affected side from before backwards. I have dwelt with some degree of minuteness on the disease of the hip-joint, which commences in the cancellated structure of the bone; but the synovial membrane, as well as the cartilaginous coverings of the femur and acetabulum, may also become the primary seat of disease; and to these diseases I will direct your attention at some future period.

I will now mention to you some of the complaints with which the disease of the hip may be confounded. One of these is an affection to which children are subject at the time of dentition. A mother will bring you a child with supposed disease of the hip; on inquiry, you learn that the child could walk at the usual period, but that when eighteen or twenty months old, he was unable to

stand, and that the child at this time was cutting its teeth. On examination of the limb you will find it wasted, the nates of the affected side flat, and the limb, if there be any difference, a little longer than the sound one. When the child attempts to walk, it cannot raise the limb from the ground, but draws it along. Now the diagnostic mark of this disease is the absence of any pain in the joint. If you place the child on the table and press in the neighbourhood of the joint, or rotate the head of the femur, no pain is produced; whereas, in disease of the hip the pain would be great. After the period of dentition the general health is little affected by this complaint. Some years commonly elapse before the child recovers the use of the limb, but ultimate recovery may, in most cases, be confidently relied on. I know a child, now five years and a half old, who was attacked by this complaint in the right lower extremity, when at the age of a year and ten months, but who has not yet quite recovered the use of his limb. There is a case which I will now shew you, of the same affection in the right upper extremity; for it attacks the upper as well as the lower limbs, though less frequently. The child, William Newman, is now three years and a half, and when a year and nine months old, during the time of cutting his teeth, lost the use of his right arm, which was attributed to accident. I saw the case at the time, and have watched it ever since. The child is gradually recovering the use of the limb. In this case the natural temperature of the limb was lessened, but the power of sensation was not impaired. Though it is not my intention at present to enter into the treatment of this form of diseases, I may observe that local remedies are of very little use; you must occasionally give purgatives and tonics, if the child requires them; but above all, you must impress on the minds of the parents, that a considerable length of time will be required for the cure.

There is another form of disease which may be readily mistaken for disease of the hip; and it occurs in nervous females, either just at the time when menstruation may be expected to commence, or afterwards, when some irregularity in this function has taken place. The patient complains of great pain in the hip, which extends also to the lumbar region, and down the thigh to the knee, a pricking sensation, and coldness in the affected limb, and an inability to walk. There is also great nervous agitation, either affected or real, in these cases. Pressure in the region of the hip occasions great pain; but whatever part you touch appears equally painful, whether over the joint or near to it; the bowels are costive, and the catamenia irregular. Now, in these cases, there is a great tendency to contraction, either of the thigh on the pelvis, or of the leg on the thigh; and unless you take means from the com-

mencement of the disease to counteract this, you will have more trouble with the subsequent deformity than the original complaint. I attended, with Mr. Harkness, sen., a young lady at Limehouse, affected with this complaint. Before the patient was placed under our care, the case had been mistaken for disease of the hip, and *moxæ* had been applied. The most positive assurance on our parts could scarcely remove the impression, which existed in the minds of the anxious parents, of there being no organic disease in the joint, and of there being no necessity to pursue the counter-irritant plan of treatment, which had been begun. The knee was very much contracted, and a good deal of trouble was experienced in straightening it. Three years and a half have elapsed since the first attack of the complaint, and the patient (though she has been slowly improving) is not yet recovered. My attention was first directed to this peculiar form of disease by the perusal of an able article in Dr. Johnson's *Medico-Chirurgical Review* for June 1828, in which cases of this complaint attacking the knee are related. I have met with three cases since that time—two of the hip and one of the knee. I hope that from this description, which I have given you, you will easily distinguish between this nervous affection and diseases of the hip. In the former the pain is felt, from the commencement, in the hip, and is not confined to the joint, but is diffused over the whole region, extending to the loins and to the knee. The patient is also unable from the first to walk. The great nervous agitation, the state of the intestinal and uterine secretions, and the unaltered position of the trochanter major, will convince you that the case is not one of disease of the hip. "There is one circumstance (says Dr. J.) attending this hysterical affection of the joints, which is calculated to mislead practitioners—namely, their being, for the most part, consecutive to a blow or injury. The fact is, that it is generally some cause of this kind which determines the local habitation of the hysterical leaven that is lurking in the constitution." Local remedies are, I believe, of very little use. I have tried *Empl. Belladonæ* and the *Emp. Opii*; friction, with both anodyne and stimulating linaments, and electricity; and I cannot say that I have seen any benefit derived from their employment. Our chief dependence ought to be placed on those internal remedies which give tone to the system and improve the secretions from the alimentary canal and uterus. The ammoniated, or the muriated tincture of iron, given in some light, bitter infusion, will be found serviceable; and if the bowels be costive during the use of this remedy, purgative injections, containing a solution of *socotrine aloes*, of a strength proportioned to the age of

the patient, should be daily administered. The bowels should be kept well open, for the symptoms of the disease are invariably aggravated when the bowels become costive. The compound decoction of *sarsaparilla*, combined with the compound decoction of *aloes*, will sometimes agree very well with the patient. If there be much hysteria, the tincture of *valerian*, combined with the *vinum aloes*, may also be tried with benefit. Warm salt-water bathing was tried by one of my patients with great advantage.

The last affection which I shall mention as likely to be mistaken for hip disease, is *psaos abscess*, of which I have a case now under my care in this institution. The diagnostic marks between the two diseases have been thus arranged:—First, in *psaos abscess* the patient complains of violent or dull pain in the region of the loins, which is very much increased in the upright posture of the body, and every motion of the limb, particularly on extending it. In the diseased hip there is no fixed pain in the loins; it is felt more in the neighbourhood of the hip, and especially in the knee. Secondly, in *psaos abscess*, during the whole course of the complaint, there is no deviation to be perceived in the natural situation of the trochanter, and no difference in the length of both limbs. In diseased hip, on the contrary, this is always the case. Thirdly, in the affection of the *psaos* muscle, the patient cannot turn the foot of the affected side outwards, without increasing the pain; whereas, on the contrary, in diseased hip the foot is generally turned outwards. Fourthly, on taking a deep inspiration, on coughing, crying, and in the erect posture of the body, the fluctuating swelling either on the nates or on the front of the thigh increases; and the exit of the matter, if the abscess be burst or opened, will be facilitated; but in abscess of the hip-joint from disease, neither is the case. In both diseases, however, the general health is very much deranged.

Treatment of Disease of the Hip.

It is very material, in our treatment of the disease, to distinguish between those cases which occur in strong subjects and those which occur in persons of a *scrofulous* habit; not only as it regards the employment of remedies, but also the result which we may anticipate. In strong persons, blood should be abstracted from the neighbourhood of the joint by cupping, and the quantity of blood must be regulated by the extent of the disease and the strength of the patient. The abstraction of blood in this manner, together with rest (for this is most essential in disease of the joints), will, if you are consulted early, be often sufficient to arrest the complaint. In *scrofulous* subjects, on the contrary, even in the early stages, the taking of blood is seldom advisable; but the applica-

tion of blisters I always resort to, and have frequently seen blistering, combined with rest, alone sufficient to stop the disease. Even in the second stage of the affection, I should place my chief reliance on these remedies. But if, in spite of the means which you employ, the complaint proceeds, you must, in the first class of patients (I mean those not tainted with scrofula), resort to the use of moxæ, or issues. I should prefer the former. One of the main objects of Professor Rust, to whose work I have often called your attention, is to recommend the use of the ferrum caudens, or the actual cautery, in this stage and this form of disease in the joints. I had, for a long time, the opportunity of seeing this practice at Berlin, and of watching the effect of this mode of treatment, and can bear testimony to its beneficial results. But this remedy is of too formidable a character, even in appearance, to make much way in this country; nor, indeed, would it on the Continent, but the hospitals there are under the control of the government, and the patients must submit to whatever is prescribed for them. The moxæ, however, I think, will answer every purpose; and two should be applied near to the trochanter, and a copious discharge kept up from them. Now, in scrofulous subjects, as we commence with the counter-irritants, and have not succeeded by their use to stop the disease, it is evident that we must resort to some other plan of treatment. I shall be disposed, in future, to give iodine a fair trial in scrofulous diseases of the hip. I shall give it internally; and after trying blisters, shall (if the patient can bear it) employ friction, with the hydriodate of potass ointment, on the joint. From the success which has attended the use of this remedy in other forms of scrofulous disease, I think we may anticipate beneficial results from its trial in this. Indeed, M. Lugol, in his Memoir, which has been recently translated by Dr. O'Shaughnessy, mentions three cases of disease of the hip cured by iodine. The iodine was exhibited internally, ioduretted injections were thrown into the fistulous openings, and the sores dressed with iodine ointment. I must refer you to the work itself for the formula of these different preparations. I may also say that a tract was published by Mr. Buchanan, in 1828, on diseased joints and the non-union of fracture, in which he states one effect of iodine to be that of producing increased action of the arteries in the extremities of bones, and consequently secretion of ossific matter. Mr. Crosse, of Norwich, has also published some cases of non-united fractures successfully treated by iodine. I mention these facts merely to assist you in your reflections on the *modus operandi* of this remedy in scrofulous disease of bone. If the formation of matter takes place, poultices and warm fomentations

should be applied; and when the abscess is in a fit state, it should be opened. Ford was very adverse to the opening of abscesses near the joints, and, at page 87, says, "who has not seen the fatal consequences of opening abscesses of joints, and the quick transition of strumous indisposition of bone, cartilage, or ligament, forms a curable to an incurable caries?" It may not be always advisable to evacuate all the matter at one time from an abscess (for sometimes it attains a very large size), but there can be no doubt but that much pain is saved to the patient by opening the abscess, and not allowing it to break of its own accord. The effects which Ford has described, occurred, not in consequence of opening the abscess, but in spite of it. In this stage of the disease, you must give anodynes to allay the pain, and the quinine internally to keep up the patient's strength. The patient's diet must also be nutritious. When the active character of the inflammation has passed away, the patient will be much benefited (particularly if he has been resident in a crowded city) by change of air and removal to the sea side. The poor even, of this metropolis, can obtain this advantage, through the Margate Sea-bathing Infirmary, which, during the season, can accommodate as many as 180 patients at one time. The building is now enlarging, and a much greater number will in future be able to obtain admission. It is folly, however, to advise a change of air and sea bathing if there be much pain in the joint, and signs of active inflammation going on; it is only when the case becomes of a chronic character, and is uncombined with pulmonic symptoms, that advantage can be expected from the change. Gentle purgatives must be given as often as the case requires them. There are several other points to which I intended calling your attention, among which is Mr. Scott's mode of treating diseased joints; but I must defer the consideration of them to some other opportunity.

CASE OF

MANIA FROM EXHAUSTION,

With Observations.

By MARSHALL HALL, M.D. F.R.S.E. &c.

To the Editor of the London Medical Gazette.

"*Palmar qui meruit, ferat.*"

SIR,

SOME time ago I had to set that eminent lecturer and physician, Dr. Elliotson, right on the subject of an infantile dis-

ease, resembling hydrancephalus, but arising from exhaustion. Dr. Elliotson, and I think Dr. Graves, of Dublin, had attributed the first detection and public notice of this infantile disease to the late Dr. Gooch; whereas, Dr. Gooch himself expressly states, that that merit (be it great or small) is due to me. In Dr. Gooch's treatise, he expresses himself in these terms:—"I sha'll not encumber this paper with a multitude of cases, but state that the above are specimens of a class, of which I have seen enough to convince me, that they deserve the attention of the profession. If I had any doubt about this, this doubt would be removed by the fact, that Dr. Marshall Hall has already recognized them, and described them in a paper which has been read at the Medico-Chirurgical Society*. He has, therefore, anticipated me in announcing them†," &c.

I should not have reverted to this subject, had I not seen a repetition of this error, in a recent work, by Dr. Billing. At pp. 47 and 110, of his "First Principles of Medicine," that gentleman ascribes the first description of the disorder in question to Dr. Gooch. In fact, I first noticed and described it in 1825.

The same unwelcome task of claiming for myself what is given to another, is imposed upon me by a paragraph in Dr. Seymour's lecture, published in No. 104 of your journal. Dr. Seymour observes:—"In the cases [of mania] arising from childbed or during nursing, Dr. Gooch has very clearly demonstrated, that these occur either in consequence of, or during, an exhausting process, and are relieved by tonic and antispasmodic medicines and restorative diet."—P. 118.

Now, sir, if you will turn to Dr. Gooch's valuable work, p. 128, you will find that that gentleman again distinctly gives me the credit of first tracing puerperal mania chiefly to exhaustion.

To say the truth, Dr. Gooch did not do this quite fairly, and on this very point I addressed a note to you, which appeared in the Medical Gazette for July 1829; and this note produced a private letter from Dr. Gooch, which, with the exception of its being addressed to me instead of to you, was highly satisfac-

tory to me, and not a little complimentary.

As I shall probably not notice this topic any more, I may just add here, more distinctly than before, and once for all, that there is a coincidence in Dr. Gooch's views and my own, upon a variety of subjects, which is too extraordinary to admit of being referred to mere accident. And as my publication preceded that of Dr. Gooch, it has always appeared to me that the circumstance should have called either for some explanation, or for some further acknowledgment. For instance:—

I have observed that the effect of remedies, and especially the degree of tolerance or intolerance of loss of blood, becomes a source of diagnosis of cases similar in their general aspect. Dr. Gooch observes, "the effects of remedies on a disease, if accurately observed, form the most important part of its history; they are like chemical tests, frequently detecting important differences in objects which previously appeared exactly similar*." Dr. Gooch and myself have alike cautioned the young physician against mistaking some of the morbid effects of loss of blood for inflammatory affections†. We have both traced puerperal mania, chiefly to mingled intestinal derangement and exhaustion, deducing thence its appropriate mode of treatment‡. We have equally concluded, from our respective observation, that puerperal phrenitis is comparatively a rare disease§. We have alike described two kinds of puerperal diseases, of which the first requires and bears depletion, while the second is characterized by intolerance of loss of blood||. A farther coincidence occurs in our views of the condition of the general system in chlorosis¶. Lastly, Dr. Gooch has made similar observations on a "hydrancephaloid affection of infants," arising from several sources of exhaustion, but "erroneously attributed to congestion of the brain**."

Such coincidences in the conclusions of persons observing the same objects

† Account of Diseases peculiar to Women, p. 365.

independently of each other, must generally prove those conclusions to be just. It is true I had sent Dr. Gooch a copy of my work immediately on its publication, and my paper on the hydrecephaloid affection of infancy had just been read before the Medico-Chirurgical Society, and noticed in the journals.

But these are matters of mere private concern, and I hasten to the discussion of a point of more general interest.

Dr. Gooch asks the question—"Would an equal or a greater degree of exhaustion occur at any other time?" (*i. e.* than after delivery). "This is a question of fact which I should answer in the negative*."

I, on the other hand, would answer, yes. And this leads me to the detail of an interesting case which occurred to me, conjointly with Mr. Yates, of 17, Gower-Street, a short time ago.

The patient was in an almost bloodless state, from chlorosis; in this condition she became affected with pneumonia, and bore blood-letting well; and lastly, after perfect recovery from her inflammatory disease, she became affected with mania, which, I believe, no one could have distinguished, except from the history, from puerperal mania. There were considerable powers of bearing the loss of blood, even in chlorosis, under the influence of pneumonia: when the inflammatory affection had subsided, the patient became susceptible of loss of blood, and experienced one of the forms of exhaustion, namely, mania.

But the case is so interesting, as to deserve to be detailed more minutely. For the following particulars I am indebted to Mr. Yates, who conducted the patient through her illness with the greatest attention and skill.

"My dear sir,—The following is an outline of the case you requested me to forward you, illustrative of mania occurring after depletion.

"On the evening of the 22d of January last, I was requested to visit L. A., aged 26, who was represented to have been ill from cold several days. I found her suffering greatly, with impeded and painful respiration, flushed cheeks, accelerated pulse—in fine, with all the symptoms of severe pneumonia. I bled her to fainting, whilst sitting upright in her chair; this took place after the loss of about twelve ounces of blood. Pur-

gatives and sudorifics were prescribed for the night.

"I paid an early visit on the morning of the 23d, and was informed she had remained faint nearly an hour after the bleeding, and had breathed more freely, and with less pain. The blood was cupped and buffed. Twelve leeches were directed to be applied to the chest. During the forenoon the symptoms resumed their formidable aspect; and when I had the pleasure of meeting you in consultation, it was deemed proper to bleed her again, and that she should take a grain of the tartarized antimony every hour until tolerance of the remedy should be induced. Venesection was performed in the erect position, and fainting again occurred when about fourteen ounces of blood had flowed. This with the powerful effect of the antimony, gave relief during the remainder of the day; but when I saw her again late in the evening, I felt called upon by a renewal of symptoms to have further recourse to the lancet; and again our patient fainted and was relieved.

"The 24th was passed tolerably satisfactorily, without depletion. The bowels were relieved by appropriate medicines, and the effect of the antimony appeared sufficient for our purpose.

"On the 25th, the pain and difficulty in breathing were more urgent; our patient was bled again to fainting. In the evening the same remedy was required, and was followed by a similar effect. The tartarized antimony and aperient medicines were continued.

"26th.—The last basin of blood, containing about twelve ounces, was free from any of the inflammatory appearances so strongly characterized in all the former bleedings. Respiration free, with only a little pain in the left side, for which twelve leeches were applied; they bled copiously, and produced fainting. I prescribed the digitalis.

"27th.—Better in every respect; saline and aperient medicines were substituted for the digitalis.

"From this time our patient became, progressively, apparently convalescent. She was soon able to sit up, though strictly enjoined to use no further exertion; her diet was rigidly prescribed, her appetite being exceedingly good; her bowels regularly influenced by medicine, and the secretions healthy. Indeed the strictest attention was paid to every thing connected with her re-

* Account, &c. p. 128.

storation to health, and I observed nothing to call forth particular notice until the 17th and 18th of the following February, when she complained of great nervousness, being giddy, and occasionally forgetful of what she was saying or doing. I attributed this, at the time, to her weak state, and to a little alarm which had been excited by my having been called in during the night of the 15th, to attend the principal member of the family, who had become suddenly indisposed. I prescribed for her small but frequently repeated doses of ammonia, opium and camphor, and a mild aperient, which had apparently the effect of quieting her.

"On the forenoon of the 19th of February I was requested to visit her immediately, but having left home early, I did not receive the message till the afternoon, when I found her in a state of the greatest excitement, with flushed face, hurried respiration, rapid pulse, incoherence of conversation, and confusion of ideas, amounting to mania. I had some difficulty in pacifying her to obtain from the alarmed attendants an account of the accession of these symptoms. It was represented that she had passed a restless night, and awoke in great agitation, and exclaimed she had seen a vision in her sleep, which impressed her with the idea of her having but six hours to live. Under such a delusion, she prevailed upon her attendants to send for a clergyman to administer to her the sacrament, who, seeing the state of her mind, very properly refused the rite. This was a new source of hallucination. She then could not die till I had seen her; and on my visit she hailed me as her deliverer from "the toils of earth and the wiles of Satan." I succeeded so far, by gentle persuasions, and unlimited promises to endless entreaties for relief, as to prevail on her to return to her bed. I prescribed sedatives, and enjoined quiet and restraint. In the evening of this day you saw her, and will, I have no doubt, recal to your memory the religious madness you witnessed, which although wild and fantastical in the extreme, still bore traces of a mind stored with something like sacred philosophy, as well as history, blending and confusing the real and the unreal with a skill which would bid defiance to the powers of a sane and superior order of intellect. A state of watchfulness, with con-

stant raving, supervened during the night, notwithstanding the administration of thirty minims of the tincture of opium, and fifteen minims given every two hours. The hair was cut off, and a spirituous lotion applied to the head.

"20th.—Symptoms little or not at all relieved. The opium was given in effervescing draughts, to allay the influence it had exercised on the stomach.

"21st.—Symptoms the same. Opium prescribed in substance. Cold applications to the head.

"22d and 23d.—State of the mind, if any change, rather more tranquil. Aperients required. Cold to the head. Opiates. Circulation more quiet, with more power.

"For a few days the state of the patient was almost stationary, the treatment remaining the same. About the beginning of March there was evident amendment in the bodily health, and the mind was susceptible of reasonable impressions, if made with calmness, perspicuity, and firmness; indeed, being given to understand that her health was now depending for restoration entirely upon the quiet of her mind, she exerted herself amazingly, and is now gradually recovering, being able to sit up for some hours during the day. Good appetite; quiet nights, with refreshing sleep; and muscular power daily improving.

"Will you allow me one minute more, my dear sir, to mention an anecdote displaying at once the power and the mystery of mental operations. Our patient was asked, in one of her raving fits, what o'clock it was? "So, so," was the reply, "and you asked me because you thought I was mad, and could not tell you." The clock was opposite her. She answered correctly, divined the meaning of her interrogator, and lapsed immediately into a train of maniacal wanderings.

"I remain, &c."

Upon this case I would observe, first, that had there been no pneumonia, a chlorotic person would not have borne so well the immediate loss of blood; and, secondly, that had there been no such loss of blood, there would have been no such occurrence of mania. At least such are the conclusions from the case, drawn both by Mr. Yates and myself. The case illustrates, therefore, many points of great practical importance.

Delirium, or transitory mania, from

loss of blood, is an occurrence of great frequency. That continued mania may arise from a similar cause, is not less true, though it be less frequent.

Puerperal mania was, then, first traced to exhaustion as a principal, not the sole cause, by myself. There are abundant proofs of the fact in Dr. Gooch's admirable volume. That other causes co-operate, is equally true. This is frequently the case with intestinal derangement; and that the state of the sexual system has much to do with it, is obvious from the mere fact and character of that form of the disease termed nymphomania.

I am, sir,
Yours very truly,
MARSHALL HALL.

14, Manchester-Square,
Nov. 7, 1831.

AN INQUIRY
REGARDING
THE CAUSES OF PHENOMENA.

BY

WILLIAM ADDISON, F.S.L. &c.

Surgeon to H. R. H. the Duchess of Kent, at
Malvern.

*To the Editor of the London Medical
Gazette.*

SIR,

THE following observations were not intended for immediate publication; but as I have, in common, no doubt, with most of your readers, been much interested by the remarks of Dr. Prout and Dr. Philip, and as they have some bearing on the matter at issue, I place them at your disposal. I need hardly observe that they were written before the remarks referred to were published in the Medical Gazette.

I am, Sir,
Your obedient servant,
WILLIAM ADDISON.

P.S. I have not altered the word *metaphysical*, to which I perceive Dr. Philip objects.

THE elements of all human knowledge are to be found in the phenomena or effects exhibited by matter to the organs of the senses. These phenomena are arranged into three classes—physical,

vital, and intellectual, and by reflecting upon them, we are led to contemplate their causes in certain energies or forces from which, in conjunction with matter, they seem to arise. But it will be necessary, before we proceed to the consideration of these forces or causes, to shew the different senses in which the word *cause* is used:—1stly, it is applied to various occult and metaphysical energies or forces, such as the electric fluid—magnetic fluid—principle of affinity—nervous fluid—vital principle—organic agent, &c.;—2dly, it is given to any phenomenon which invariably or generally precedes another, as when we say, heat *causes* fluidity—atmospheric pressure is the *cause* of the Torricellian vacuum—gravitation is the *cause* of atmospheric pressure—wind *causes* the waves of the sea—variation of temperature *causes* wind, &c. In these latter instances we find that certain phenomena, because invariably or generally followed by certain other phenomena, are entitled *the causes* of those succeeding. Now the term *cause* here is applied in a way very different from that in which it is used in the instances first mentioned; for we say *atmospheric pressure is the cause* of the Torricellian vacuum, and also *atmospheric pressure is the effect* of gravitation—wind is the *cause* of the waves of the sea, and wind is the *effect* of variation of temperature; so that here these phenomena play a double part, standing as *causes* to those phenomena which succeed, and as *effects* of those which precede: in these instances, then, the word *cause* merely implies that such and such phenomena invariably or generally precede such and such others.

When we treat upon the subject of cause and effect philosophically, it becomes a matter of some moment not to lose sight of this important distinction; and it would tend much to simplify a difficult inquiry, if we were to lay aside the term *cause* when referring to the *order of succession* in phenomena: thus, if instead of saying, the motion of a steam engine is *caused* by steam—steam *caused* by heat—heat *caused* by chemical decomposition, and chemical decomposition by chemical affinity, we were to say, the motion of the engine is *preceded* by the production of steam—steam *preceded* or accompanied by heat—heat by chemical decomposition, and so on, the doctrine of causation would be placed upon a more intelligible basis,

and no phenomenon or object of sense would then be admitted among *causes*; for this term would (under this, as I conceive proper limitation,) always refer us to something preceding every phenomenon, and therefore something very different from any phenomenon or effect whatever.

Subject to this limitation, then, I shall proceed to develop our notions regarding causes, and endeavour to point out the influence these notions produce upon our philosophical pursuits and experimental researches.

With regard to physical phenomena, we speak of *force of gravitation—principle of attraction—electric fluid—magnetic fluid*, &c. as though there were many recondite agents or metaphysical forces engaged in the production of these alone; but the progress of scientific pursuits, and the discovery of many previously unobserved phenomena, have developed so many intimate connexions, that we are induced to believe all physical phenomena subject to one pervading cause, force, or energy, operating in different ways, determined by differences in the conditions or nature of the matter through which they appear.

I consider it unnecessary to detail the several discoveries by which our notions respecting the causes of physical effects have become so generalized as to induce us to admit, that they arise from *one pervading force*, which regulates, at the same time, the motions of those immense masses revolving through space, produces the effects of electricity and magnetism, and controls those extraordinary combinations and arrangements observed in our chemical pursuits; it is sufficient to remark, that every new discovery and every new fact confirms the idea. Whether this all-pervading force, controlling physical phenomena, can exist independent of matter, it is impossible to know, or what matter would be without it, useless to inquire; but as long as they are conjoined, nothing can be more incorrect than to speak of matter as inert. Because we do not see particles and masses wheeling about or stalking around us—because we do not witness one body rising up, and moving towards its neighbour, we content ourselves with regarding them as composed of inert materials; while we neglect the movement of atoms in every chemical change—the marching of particles in crystallization seek-

ing light—and the strides of masses in their revolution through space, and forget that the motionless state of matter which we notice, is one of the most obvious effects resulting from that cause, force, or energy, with which it is endowed. But are we to believe, I would ask, that the operations of this active and *powerful cause* stop here; and to suppose that, although capable of producing all the wonderful phenomena of inorganic matter, it is entirely superseded by another more energetic in the phenomena of vitality? are growth, function, and nutrition, in organized bodies, under the dominion of a totally different cause from that giving rise to gravitation, polarity, and crystalline form? A negative to these questions seems indicated by those striking connexions between physical and vital phenomena, which the progress of science daily reveals, and forces upon our notice. The growth and nutrition of vegetable and other organic matters differ much, it is true, from most physical phenomena; but so does the formation of a salt differ from the combustion of coal; and if, in the course of our inquiries, we see reasons to refer such dissimilar effects as electricity and crystallization to one great metaphysical cause, what are the reasons why we should deny its operation in the formation of organized structure? The analogy between this structure and crystallization may be much more complete than we usually imagine. A crystal cannot increase in size, or become perfect in its form, without being furnished with saline particles under certain peculiar conditions: in fact, a crystal may form in a solution, may continue to increase to a certain bulk, and then diminish or dissolve: in the former case it may be said to grow or be nourished; in the latter, to die or be starved. A plant, to grow and flourish, requires a certain quantity of moisture; and, as long as the required supply is furnished, it thrives, but, deprive it of this, it languishes, and ceases to live; in fact, plants do not possess the power of overcoming the more ordinary physical affinities in a much greater degree than a crystal; for, as a solution, in which the latter is beginning to dissolve, may contain many saline particles, so the earth and the air, in which a plant is dying for lack of moisture, frequently contains a very notable quantity: the

crystal is unable to combat the affinity of the water for the saline particles, and the plant cannot overcome the attraction of the earth and air for moisture.

Crystallization, it may be said, bears no affinity to vegetation, inasmuch as it is merely the aggregation of particles existing previously in solution, and in nowise altered by the process; but this only shews that crystallization is a more simple species of vegetation than that exhibited in the growth of organic matter; for a vegetable body can create nothing new, its productions resulting only from the aggregation of certain particles existing in the soil, air, or water, by which they are surrounded. Still, it may be remarked, that we can accomplish nothing similar to the productions of organic matter by chemical manipulation. This, however, is not altogether true, for some of them have been produced in the laboratory, and probably ere long there may be many more. The efflorescence occurring on the surface of iron pyrites, or alum slate by exposure to the air, and the arboriform production of lead when zinc is suspended in its solution, are phenomena allied to vegetation: decompositions and re-arrangements of particles in these instances take place, presenting all the phenomena embraced by the term growth. From a mingled solution of two or more salts, the crystals of one or more may be obtained separate and distinct by due evaporation and rest: here, then, a crystal may be said to grow out of the solution, certain particles joining themselves together, to the exclusion of others. But living matter, it may be said, is capable of controlling the operations of the cause of physical phenomena; so we find it in bodies of a crystalline structure. A piece of alum suspended in water is not equally dissolved at all points; the same power which preserves the vegetable form from decay, also preserves the crystal from solution, so that we find the surface of the alum unequally acted on, the resisting points presenting a regular and determinate arrangement. If we place any inorganic substance within the influence of electric currents, by a galvanic apparatus, we find its ordinary habitudes and relations destroyed or interfered with, as when an acid passes through an alkaline solution without combination: in this case our instru-

ment produces an effect analogous to that which the vegetable apparatus does, conferring on particles of matter new affinities and new powers of combinations, or, to speak more correctly with the views herein taken, directs the power controlling matter into new channels and new methods of display. The great and powerful influence of light upon many physical and almost all vital phenomena, is another point of connexion not to be forgotten: it induces many chemical combinations, and materially promotes the process of crystallization; it is essential to vegetation, and even animals become sickly and diseased if deprived of it for any time; many saline crystallizations comport themselves with light in a way precisely similar to vegetation, turning towards and seeking the direction in which it comes. The phenomena of endosmose and exosmose also point out various intimate relations between physical and vital effects not to be overlooked or forgotten.

The surface of the earth, I conceive, may be regarded as the bottom of a capacious vessel spread over with various kinds of matter, in contact with superincumbent fluid; while vegetation may be considered as an efflorescence protruding from the ground, and matured in the air in a manner analogous to crystals in a solution, or on the surface of alum, slate, or pyrites—certain forms of matter, in both cases, shooting up or growing with fixed or determinate figures, the elements of which exist partly in the substance or seed forming the basis from which they arise, and partly in the air and moisture surrounding them. Crystals will not grow or appear on alum slate without air and a certain quantity of moisture; so a seed will not germinate, nor vegetation continue, but with the same matters. Alum slate and pyrites contain materials, the chemical repose of which is disturbed by a little air and a drop of water; so a seed may be likened to a little case containing matters so delicately balanced that a little air and a little water overturns their affinities, and germination takes place. In the case of the alum and pyrites, too much water interferes with or stops the process of crystalline efflorescence; so in the seed, too much moisture is unfavourable to vegetation, and, instead of promoting the peculiar changes of the plant, renders their component matters amenable to the more

ordinary phenomena of corruption and decay.

It was by slow steps that the connexion between the various, and at first view, totally dissimilar physical phenomena, were pointed out. Electricity and magnetism for a long time stood aloof from each other, and from the rest of their class; so, therefore, we ought to expect that many hitherto unobserved phenomena must present themselves, before the relations in which physical and vital phenomena stand with regard to each other, are fully acknowledged or understood, notwithstanding the progress of science is daily narrowing the breach, and forcing upon our notice important connexions between the operations of organized and inorganic matter. Nevertheless, as recent discoveries have brought together under *one cause* the dissimilar physical phenomena, so have we every reason to anticipate the same kind of union between these and vital phenomena; so that instead of two distinct classes of effects, with distinct hypothetical and metaphysical causes, we shall find that all we witness agrees in obeying one principle, controlling the phenomena of the world*.

There are some persons, perhaps, who may admit, that the phenomena of organic and inorganic matter have many important connexions, and that *one cause* may operate throughout, who, nevertheless, are not so far influenced by the consequences to which such an admission leads, as to perceive that the terms in constant use to designate the causes now allowed in our reasonings and researches, such as organic agent, nervous fluid, vital principle, electric fluid, magnetic fluid, principle of attraction, &c. are arbitrarily used, serving only to link together a few of the more obviously connected phenomena, and as applicable to one set as another: thus we appropriate to the *organic agent*, circulation, secretion, and nutrition, in animal bodies; to the *vital principle*, the phenomena of vegetation; to the *electric fluid*, electrical phenomena, &c.

But it must be clear that as these terms refer us to agents of which we know nothing, except by the phenomena pre-

senting themselves to our senses, so, therefore, any distinction or difference between them must rest solely upon the distinctions and varieties of these phenomena; and, consequently, according as connexions and relations between different classes of phenomena are discovered or pointed out, so will our terms applied to causes coalesce or diminish, as appears already in the instances of electric and magnetic fluids, principle of attraction and chemical affinity; so many important relations between the classes of phenomena, at the head of which these stood as *causes*, having been discovered, that we are brought, as I have before observed, to refer them to *one active principle*. Under these circumstances, it must evidently be unscientific to declare positively, that there can be any difference or distinction between the object referred to by the terms, organic agent, vital principle, or electric fluid; on the contrary, from what is daily occurring in the progress of philosophical pursuit, we are led to anticipate that these terms, although now (from our not having discovered sufficient connexion between the classes of phenomena to which they stand as causes) they appear to refer to forces or energies distinct from each other, may be traced (when more *hitherto unobserved phenomena* become known) to *the one cause* operating throughout. Indeed, even in these latter instances, such connexions are discovering themselves between the several classes of phenomena at the head of which they stand, that we hear persons affirming that electric fluid, galvanic fluid, nervous fluid, and organic agent, denote the same power; thus, in fact, acknowledging it a mere question of convenience whether we apply the term electric fluid, principle of polarity, vital principle, nervous power, or organic agent, to the cause.

The utility of these speculations upon the connexions between phenomena, as modifying our notions of *causes*, and as leading to the existence of *one energy* prevailing throughout, may not at first view appear; but we should remember, that all our observations and modes of expression in scientific matters, as well as our experimental researches, are materially influenced by our opinions respecting the *causes* of phenomena, and therefore that we ought, where both sides of the question are involved in ob-

* The reader will understand that my observations relate only to physical and vital phenomena. Intellectual phenomena and mind, may form subjects for future consideration.

security, to keep to that which tends most to stimulate us to further exertion. If we acknowledge but *one cause* for physical and vital phenomena, we shall eagerly enough seek for the connecting links between them, instead of slowly and reluctantly admitting those which begin now to forcibly arrest our attention. A reluctance arising from the idea that *the cause* of vital effects is very different from that controlling physical phenomena, and beyond the reach of experiment, is what tends very much to retard our advancement in the higher branches of philosophical inquiry, because it leads us to neglect those connexions or relations between dissimilar phenomena, which will doubtless reward the labours of industrious inquirers.

ABSCESS OF THE BRAIN OPENING EXTERNALLY.

To the Editor of the London Medical Gazette.

SIR,

I HEREWITH transmit a case of abscess of the brain, occurring in a boy eight years of age, which, if you think worthy of record in your very valuable publication, is much at your service.

I am, sir,

Your obedient servant,

S. G. LAWRENCE,

Surgeon, Royal Military Asylum, Chelsea.

Nov. 21st, 1831.

Duncan McCraig, aged eight years, was admitted into the Royal Military Asylum, Chelsea, on the 24th of October last, when he appeared to be in good health. On the following day he was brought to the hospital, on account of refusing his food. He made no complaint but of want of appetite; had no febrile symptoms. Tongue clean; pulse natural. A purgative was given; and on the 26th he was dismissed, having no apparent complaint. On the 31st October he was again brought to the hospital, still having no constitutional disturbance; but it was observed that he was inactive and dull, continuing to refuse his food; he now also complained of headache, particularly on the left side of his forehead; and at this part, about an inch above the superciliary ridge of the frontal bone, there was a small in-

flamed boil, from which a few drops of pus were pressed out. On being questioned whether he could account for the pain in his head, he said he had had a fall in the street a week before his admission here, and struck the left side of his forehead against the ground; but the skin was only slightly grazed, and he neither felt sick at the time nor afterwards. His tongue was clean; bowels torpid. A dose of scammony and calomel was given him, and a bread poultice applied to the boil on his forehead. In three days the boil was healed, very little discharge having come from it, and only a small cicatrix remained.

During this time he did not complain much of his head, and was walking about the ward like the other boys with trifling complaints. No alteration took place until November 6th, when febrile symptoms appeared; the tongue was slightly furred, skin hot, and increased pain in his forehead. Leeches were applied to the temples, a brisk cathartic of jalap prescribed, followed by saline medicine. There was nothing unusual in the alvine discharges. This was the first day that any serious affection of the head was indicated.

7th.—The febrile symptoms were much moderated, and he said his head felt better; he dozed a great deal, and disliked to be disturbed, but was perfectly sensible, and the pupils of his eyes were of natural appearance.

8th.—This morning his pulse was found to be remarkably slow (60 in a minute); tongue more furred, and his bowels were torpid. He did not complain much of his head, but when he did he always pointed to the left side of his forehead. An emetic of ipecacuanha was prescribed, followed by calomel and rhubarb. At the evening visit, seven o'clock, the emetic had operated gently, but little was discharged; and he had had two scanty alvine evacuations. Pulse 60, small, as in the morning; skin of natural temperature, and he appeared to be in a tranquil sleep. During the night the nurse, hearing him make a moaning noise, went to him; he was perfectly sensible, spoke to her, and said he did not want anything. At six o'clock the following morning (Nov. 9th), the nurse found him dying, and he soon after expired.

Examination of the body 29 hours after death.—On reflecting the scalp

from the bone, particular attention was directed to the left side of the os frontis, where the boy had complained of most pain. A small carious perforation of the bone was there perceived, about an inch above the superciliary ridge, which would admit a small-sized probe; and the bone round this hole had a dull red appearance, apparently from increased vascularity. The internal surface of the scalp had a small dimple-like depression, corresponding to the hole in the bone, and the minute cicatrix on the skin of the forehead, left by the healing of the boil. The calvarium was now removed, and which adhered less strongly to the dura mater than is usual in young subjects. On the internal surface of the os frontis a small prolongation, about the thickness of a probe, was seen proceeding from the dura mater to the perforation in the bone, resembling a vein or vessel entering it; immediately above which was a small spot of ecchymosis on the brain, about the size of a sixpence. The dura mater was now reflected; no particular vascularity or turgescence of the vessels of the brain was observed; but the anterior lobe of the left hemisphere appeared of a straw, or greenish-yellow colour, evidently denoting the site of an abscess, with distinct fluctuation when pressed. The posterior lobes were of natural appearance, as well as the whole of the right hemisphere. The right side of the brain was now sliced down to the lateral ventricle, on opening which a small quantity of limpid fluid escaped. Attempting to do the same on the left side, the brain gave way, and about *two ounces* of bland inodorous pus gushed out, and the cyst of an abscess became apparent. The posterior part of the left lateral ventricle was also found filled with pus; but it was difficult to say whether it had existed there prior to death, or took place from the bursting of the cyst of the abscess during the dissection. The thinnest part of the cyst was at the anterior part, near the ecchymosed spot, just above the perforation in the frontal bone. The cavity of the cyst was vascular, of a dark red colour.

The cerebellum was natural. The thorax and abdomen were examined, and the viscera of both these cavities were in a healthy state; but there was a small *diverticulum ilii*, or preternatural pouch, three inches in length, pro-

ceeding from the intestinum ileum, at the distance of fourteen or fifteen inches from its termination in the cæcum—a *lusus naturæ* which, I believe, is not very common. A somewhat similar malformation, however, has once before occurred to me (among numerous post-mortem examinations), and which is recorded in the Edinburgh Medical and Surgical Journal of October 1830.

REMARKS.—The efforts of nature to make an outlet for the matter in this case are curious, and well worthy of observation. A little process or prolongation, like a duct, of the thickness of a probe, extends from the abscess and dura mater to the frontal bone, through which a perforation is made, by the action of the absorbents, to the integuments of the forehead, where a small boil forms and breaks, thus making a direct external opening, communicating with the internal abscess in the brain, which, consequently, may be said to have broken externally.

I think this must have been a chronic abscess of the brain, originating independently of the fall, although that accident may have accelerated the fatal termination; for it is scarcely probable that so large a collection of matter could have formed, and made its way externally, in the manner above stated, in so short a space of time as from the date of the fall (about three weeks), and with so little constitutional irritation.

His mother being questioned about his fall, corroborated the boy's statement, and said that it was only a slight cut or graze; a piece of plaister was applied, it healed in two or three days, and she did not consider the hurt of any importance; but added, that he was always a very delicate child, not only as regarded his food, but in many other respects, and was possessed of great mental sensibility. Having lost his father about three months ago, he had fretted much on that account, and never was playful like other children subsequently to his father's death. With regard to the suddenness of his decease on the morning of the 9th November, may it not have been owing to the abscess having suddenly burst into the left lateral ventricle? for it is to be remarked, that there were no symptoms of effusion on the brain, no dilatation of the pupils, no coma, the boy being perfectly sensible to the latest period at which he was seen prior to death.

ON THE USE OF DRY HEAT-BATHS
IN CHOLERA.

—
To the Editor of the London Medical Gazette.

SIR,

FOR the peculiar symptoms of cholera, heat seems to be regarded by most of those who have seen the disease as clearly indicated. It would be a waste of time to particularize those symptoms, as they are now familiar almost to all persons; and I take it for granted, that heat is generally allowed to be a means of remedy tending to remove them. Nevertheless, some practitioners have recorded their opinions, decriing the use of baths altogether for this disease, and assign as a reason, that they have not been successful when resorted to. This does not militate against the principle of the usefulness of heat, so clearly indicated; it only goes to prove the awkward and insufficient way by which, as a remedy, it has been applied, for as no satisfactory method has been hitherto brought before the profession, the true value of the remedy has not yet been ascertained. It is, however, a sufficient apology for those gentlemen who condemn the use of heat-baths, because much very valuable time would be lost by their ineffectual application, and consequently disappointment to the practitioner and his patient be the result.

My only object in these few sentences, is my desire of contributing some little share of usefulness at this crisis, and I hope no person will attach to me any invidious or sinister motive; for, not being a manufacturer or interested vendor of baths, such charge would be unfair. The possibility of misconstruction, however, ought not to deter me from my purpose, and I say, without hesitation, that all those baths which I have hitherto seen and tried are quite unfit for the intentions designed from their use; without exception, they are all on a wrong principle, and contrary to the laws of science as they apply to heat. Moreover, they are constructed so rudely, from a desire of making them cheap, as to tend greatly to make them useless, although, when properly constructed, they cannot be dear. In addition to the imperfections and drawbacks alluded

to, there is a greater to be named—they are by no means free from danger. During the last fortnight, two respectable and zealous manufacturers have declared to me the danger they have run of setting the bed on fire; and in my various trials, although my servants are much accustomed to these matters, a similar accident has been nearly occurring twice; nor have they, or even myself, escaped without burns. My various and persevering trials have, however, led me, I believe, to the construction of a portable calorific apparatus, free from the before-named objections. Some persons whose characters stand high for scientific knowledge, have seen and proved it, and think it leaves nothing more to be desired for the purposes expected from its use.
